may small problems:

* Learning Curve - It was my first Coax Cable [Shielded] Loop
Antenna.

* Questionable 'quality' of the old RG-59 Coax Cable being used.
[ Learned to use 'new' better quality Coax Cable. ]

* Trouble getting a good 'connection' at the Bottom-Joint between
the Aluminum Braid.
[ Learned to use more exposed Braid to make 3-4 complete Wraps
```

around the other section of Exposed Braid at the Bottom-Joint. ]

IDEA: Got the Idea for the LOOP-HUB using a 'modified' TV
type Two-Way Splitter.

* The "F" Connector' End had a Center Wire that was 'short' and
resulted in an intermittent connection when moved.
[ Learned to make sure that the Center Wire was Long Enough
and that I did NOT Bend them and Short-them-Out when installing
them. ]

The basic design of the "GreerTech" Coax Cable [Shielded] Loop
Antenna is good and very practical.
LOOP=> http://www.greertech.com/hfloop/mymagloop.html

My 'second' Coax Cable [Shielded] Loop Antenna was made from
Thirteen Feet (13 Ft) of standard size RG-8 Coax Cable.

* Big and difficult to work with.

* Easy to get a good 'connection' at the Bottom-Joint.

The most recent Coax Cable [Shielded] Loop Antenna was made from
a standard 'pre-made' Twelve Feet (12 Ft) of RG-6 'Quad Shield'
Coax Cable.

* RG-6 is 'easy' to work with.

* Pre-Made Lengths with "F" Connectors already attached.

* Just 'cut' the One Inch "Gap" at the Center of the Length.

* Easy to get a good 'connection' at the Bottom-Joint using the
LOOP-HUB made from a TV type Two Way Splitter.

RESULTS: Very Good Performance. (Equal to the 13 Ft RG-8 Loop.)

NOTE: Lessons Learned.

>From: linuxlover992000@yahoo.com (Linux Lover)
>Is it really that magical (for FM at least) as described here?
(...)
Despite the difficulties, radios can be balanced to favour any
signal on the antenna over whatever might leak through the power supply or
up the speaker wires. My sister has a table-top radio that will pick up
the strongest FM stations in her city from a twist-tie stuck into the 75
Ohm cable feed, and neither the positions of the speakers nor the
orientation of the power cord had an effect.

My point is that Lynn is pointing to an amplified antenna, and I
don't doubt that with any FM receiver but the most carefully balanced ones
that an amplifier on the antenna itself will make the signal stronger than
whatever gets into the power supply and whatever else gets up the speaker
wires.

(Speaker wires are often intentionally made into antennas for
handheld radios, so the orientation of your headphone wire and how close
it is to your body can affect FM reception).

I doubt that amplified omnidirectional is as good for weak
stations as a good directional antenna, the simple reason being that most
of the signal to amplify will be noise. It would be better to invest in a
multi-meter to see if your antenna actually has the right impedance.

So, your mileage may vary, and this amplified omnidirectional
antenna will work better with cheap equipment.

The netnews rules prohibit posting binary files. If you don't have
a web page, you could post it to alt.binary and point to it from
here.

Modeling a helical loading coil in EZNEC and putting loads at the
various segments also clearly illustrates the current taper. All
real-world air-core loading coils are distributed networks. In
a distributed network with reflections, the standing-wave currents
are tapered within a sinusoidal envelope.

Here's an unanswered question: If the loading coil occupies zero
degrees, how can the remaining eight feet of the antenna occupy
the entire 90 electrical degrees? Wouldn't the coil have to
change the frequency for that to happen?

# 1409. what dish to capture a geostat. sat shifted of 75 deg long ?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-10-27 18:03:39 UTC
From: Thierry <->
Message-ID: <417fe300$1@news.vo.lu>
Source record: 87504

Hi,

A question : how weak is a geostationnary satellite signal at the edge ?
(case study)

Imagine a geostationnary TV satellite like AMC-6 located over NY or so (72
deg W) with a signal 50 dB in area 500 km wide, decreasing down to 30 dB a
few hundreds miles offshore and thus very weak in Europe (10 dB ?)
The satellite transmits two signals : its NTSC video (vertically polarized)
near 3.88 GHz and an audio at 6.8 MHz FM mode (monaural), standard specs
used e.g. by NASA TV.

Is there a way to capture its signals from Europe (say ON) using a 2 to 4m
wide type TVRO or Quorum dish (with preamp, NTSC/PAL converter, etc) knowing
that its beam is quite narrow and the signal very weak ?
In addition a beam cut on 6.8 MHz 'd be used to capture its FM signal on HF,
the satellite being not to high above the horizon ... (supposition)
NB. In this example the longitude difference is 50-75 degrees !!

Theoretically, is it possible to built such a system being so far from the
satellite and the satellite being so low over the horizon ?
or the beamwidth of the satellite dish does not permit receiving at such
longitude differences ?

Or say in other words, has an european ham already tried to capture US
geostat satellites successfully ? and using what kind of system (RX and
antenna diam.)
or conversely, has an US ham succeeded to capture signal from an european
geostat satellite (Meteosat...) ?

What should be the minimum antenna specs to get a "good" receive (diameter,
preamp gain, without or without downconverter and then rx qrg, longitude
difference max., signal strength at receive on 2m and 4m dish...)

I think that it is possible with a dish >2m, but I 'd like a confirmation.

Thanks in advance

Thierry, ON4SKY

Cecil,

1) Only the total current matters. I have never found a detailed treatment of antennas that was based on anything other than the total current (or total current density) at each point on the antenna. Have you?

Current components may be useful for discovering the total current or for handwaving explanations, but they have no further role in antenna analysis.

2) Where did this 90 degree phase shift requirement come from? There is virtually no phase shift in the current of a half-wave dipole (or quarter-wave monopole) from feedpoint to tip. I am looking at figure 9.6 on page 370 in Kraus "Antennas" (2nd Ed.), and it shows perhaps a few degrees phase variation over the entire length of the dipole antenna. This figure is located in the chapter on the Moment Method for calculating cylindrical antennas, in case you do not have the second edition.

I suspect you may be confusing the argument (AKA, the phase) of the cosine function presumed to describe the behavior of the current amplitude. However, current amplitude and current phase are not at all the same thing.

Have you been seduced by your math models?

73,
Gene

I wrote:
"Critical coupling is defined as maximum energy transfer at the resonant frequency."

Also:
"Coupling additions (more loads) to a feedpoint lowers the impedance unless additional measures (transformations) are taken."

I`ve since consulted Terman, and critical coupling is defined as I said above. Terman adds coupled elements differently than I did above.

On page 64 of his 1955 edition, Terman defines critical coupling as:
"These trends continue as the coefficient of coupling is increased until the coupling is such that the resistance which the secondary circuit couples into the primary at resonance is equal to the primary resistance. This is called the CRITICAL COUPLING and causes the secondary current to have the maximum value it can attain."

On page 65, Terman`s statement supports Art:
"When the coupled impedance is added to the self-impedance of the primary circuit, the effect at resonance is to increase the effective primary resistance above the value that would exist in the absence of the secondary. This causes the primary current at resonance to be reduced in all cases by the presence of the secondary."

I wrongly assumed a coupled load would add to the primary current. I apologize to Art and to others who I misled.

Best regards, Richard Harrison, KB5WZI

Cecil,

In a simple monopole with one inductor, let L1 be the distance from the base of an antenna to the bottom of the loading coil in meters, L2 the length of the loading coil, L3 the distance from the top of the loading coil to the top of the antenna. I is the base current, L the inductance value and F the frequency. You can assume the antenna is very thin.

Since your theory is so elegant and well developed, and you've had such an excellent education at Texas A&M, it shouldn't be difficult at all for you to write a couple of simple equations which give the currents at the two ends of the coil. In the time-honored methods of science, your equations can then be tested against modeled and measured results to prove the validity of your theory.

Roy Lewallen, W7EL

Fine ! (a way of speaking) it's a new information for me.
OK that a >100m dish is not really realistic, at least for an amateur :-((

But the problem is also : as I am very much "out" of the main beam (say 50°
off in longitude), can I receive some signal ?
I have thought that the beam was like a cone and outside there was no
receive at all.
But you seem to say that the decreasing of signal strength is more or less
constant with distance, there is not abrupt decreasing say below 0 dB
contour or so ? right ?
Or in other words is there a maximum distance or a longitude difference over
which there is no more signal ? none ?
For short all 'd be a question of receive dish diameter... (and visibility
of the sat.) ?

Check out my tag line, Gene. Balanis says we can use the component currents If and Ib to analyze a standing-wave antenna. Kraus says essentially the same thing when he says: "A sinusoidal current distribution may be regarded as the standing wave produced by two uniform (unattenuated) traveling waves of equal amplitude moving in opposite directions along an antenna." This was in regards to the "Fields of a thin linear antenna with a uniform traveling wave."

Just because there is no "detailed treatment" doesn't mean that it should be forbidden to discuss. We are out on the edge of what has been detailed (so far) so don't be afraid to think outside of the box. The opposite phase shift between If and Ib is the cause of the decrease in coil current in a typical mobile antenna. It happens even if there is zero loss in the coil and zero radiation from the coil. It also happens in a lossless transmission line. There is a decrease in standing wave current on each side of a current maximum point even when the transmission line is lossless. The same thing applies to a lossless coil with dimensions larger than a point.

> Current components may be useful for discovering the total current or
> for handwaving explanations, but they have no further role in antenna
> analysis.

Check my tag line again, Gene. They are absolutely useful for transmission line analysis and are therefore useful for standing-wave antenna analysis.

> 2) Where did this 90 degree phase shift requirement come from? There is
> virtually no phase shift in the current of a half-wave dipole (or
> quarter-wave monopole) from feedpoint to tip.

Yes, you are talking about the standing-wave current which is the superposition of the forward and reflected currents. A 1/4WL wire is 90 degrees of a traveling-wave antenna. The forward current rotates by 90 degrees and the reflected current rotates by 90 degrees.

> I am looking at figure 9.6
> on page 370 in Kraus "Antennas" (2nd Ed.), and it shows perhaps a few
> degrees phase variation over the entire length of the dipole antenna.

Yes, that is true for the superposed forward and reflected currents and is shown to be true by my phasor diagrams on my web page. The forward current is a traveling wave. The reflected current is a traveling wave.

I'm sure you are familiar with the change in phase undergone by traveling
waves in perfectly matched systems. Apply that knowledge to the separate
forward and reflected current traveling waves and you will understand
the magnitude variation in If+Ib caused by their respective phase shifts
in the opposite direction even if their magnitudes remain constant.

> I suspect you may be confusing the argument (AKA, the phase) of the
> cosine function presumed to describe the behavior of the current
> amplitude. However, current amplitude and current phase are not at all
> the same thing.

Nope, I fully agree that the superposed net current has almost zero
phase shift because it is a *standing wave*. Traveling waves, OTOH,
experience phase shifts when traveling along a wire. The forward
current and reflected current on a standing-wave antenna are
*traveling waves*.

This is an onion-type problem, Gene. Please peal back the net current
layer and look at the component currents underneath even if you feel
presently that it will be a waste of time.

Incidentally, I bounced most of this stuff off of Dr. Balanis when
I was working with him on a joint Intel/ASU project. He agreed so
far (1995) and my extensions since 1995 are logical. If you will
take it step-by-step, I think you will agree. If you find any error
at all on my part, you will, no doubt, call my attention to it and
I will learn something.
--
73, Cecil http://www.qsl.net/w5dxp
"The current and voltage distributions on open-ended wire antennas are
similar to the standing wave patterns on open-ended transmission lines ...
Standing wave antennas, such as the dipole, can be analyzed as traveling
wave antennas with waves propagating in opposite directions (forward and
backward) and represented by traveling wave currents If and Ib ..."
_Antenna_Theory_, Balanis, Second Edition, Chapter 10, page 488 & 489

# 1416. Is there such a thing as "Best Omnidirectional FM antenna"?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-10-27 19:52:02 UTC
From: linuxlover992000@yahoo.com
Message-ID: <7687bfbd.0410271152.293fefb4@posting.google.com>
Source record: 87511

Is there a product you can recommend as "The Best Omnidirectional FM antenna"?

If so, which one is it? (brand/model and/or URL please)

Oh - one significant constraint is that it cannot be larger than about 3 feet (1 meter) in any dimension, because it is going to be installed in my attic. I know it cuts the signal by 50%, but I am willing to live with that since I am assuming that if a whip antenna on a portable radio works great in my basement, a **good* omnidirectional FM antenna in the attic must work *at least* as good...

An extensive search yielded only the Triax omni FM:
http://www.towerhillaerials.com/viewProd.phtml?ref=52&orderNumber=0
But where can you buy it in the USA?

I also found an ANTENNACRAFT FMSS at STARK Electronics:
http://www.starkelectronic.com/acantena.htm#FMSS, but the specs at that site say Boom length is 8' and Maximum Width say 55'. These can't be feet, right? They surely confused the foot symbol (') with the inch symbol (") - or did they?

Anyway, any tip you can provide on finding such an omnidirectional FM antenna would be highly appreciated. VHF/UHF omnidirectional antennas that do *not* trap the FM band with a notch filter are welcome, too.

Thanks,
Lynn

Sorry, Roy, my theory is not elegant and/or well developed. Equations may be possible in the future, but not right now. At the present time, the theory is qualitative, not quantitative. We are out on the edge of what has been published so far and are in the process of discovery. It is hard for me to believe that this material hasn't been covered some time, somewhere, in a Master's thesis or a PhD dissertation or somewhere in the IEEE proceedings. I regret that I don't have access to such.

The coil has an 'L' and a 'C' and thus can be regarded as a short piece of transmission line. For a mental picture, consider two pieces of helix material, side by side, being used as a balanced transmission line. They would certainly possess a high velocity factor as does a bugcatcher coil. Here is the equivalent of 1/2 of a typical loaded dipole using horizontal #16 wire at a height of 24 feet where Z0=138*sqrt(4h/d).

Feedpoint---Z0=600 ohms---x---coil---y---Z0=600 ohms---

The Z0 of the coil is presently unknown but I am working on getting a ballpark value for it. In any case since Z0=sqrt(L/C), the Z0 of the loading coil will be very high. That means, in addition to the reflections at the tip of the antenna, there will also be reflections at 'x' and 'y', both ways. That situation is pretty complicated but the result is apparently to put the forward voltage out of phase with the forward current at the feedpoint. It also apparently puts the reflected voltage out of phase with the reflected current at the feedpoint. The only requirement is that Vf+Vr be in phase with If+Ir at the feedpoint. I hope you can appreciate the complexity of that situation, stop asking for a "simple equation", and assist us in the apparently complicated solution.

When someone doesn't understand the topic, one asks for a "simple
equation" and when none is forthcoming, one rationalizes that the
new information is not worth knowing. How about working with me
instead of against me on this complicated problem for which neither
one of us has the complete answer (yet)?

P.S. If you had demanded a "simple equation" from Maxwell, you would
have been disappointed also. :-)

Sorry, this should have been a *LOW* velocity factor.

Cecil,

Thanks. You just validated my point. Kraus absolutely does not use component currents for any serious analysis; he uses only total current. Likewise, it appears that Balanis is merely waving his hands as well. The quote you provided comes from Chapter 10, on traveling wave antennas, not from a chapter on simple dipole antennas. Does he actually load these components into equations and carry out the analysis in detail?

Subcomponents of the current may be useful for handwaving explanations, but they are not superior to the standard net current model. Any modeling results must agree with the standard model (widely used for more than 100 years) or else the simple handwaving model is likely to be bogus.

Soooo, we are back to the beginning. There is minimal current phase shift in a dipole or monopole antenna, certainly nothing like the the 30 to 60 degree "replacement" phase shift you have been claiming. There is no mysterious "current drop". Any reduction in measured (or modeled) current can (and must) be accounted by shunt currents.

What's left?

Bye,
Gene
W4SZ

Let me get this straight. Just because Kraus didn't use component currents for any serious analysis prohibits future thinkers from doing so? Do you really believe that anything Kraus didn't choose to include in his book should not be considered by human beings like you and me? (I don't recall him saying anything about sex.) :-)

If you consider Kraus' book to be an Antenna Bible, then you are guilty of bringing metaphysics into physics.

> Likewise, it appears that Balanis is merely waving his hands as well.
> The quote you provided comes from Chapter 10, on traveling wave
> antennas, not from a chapter on simple dipole antennas.

"Handwaving - anything that disagrees with your present EM religion"

Does that prohibit you from considering the component currents? If so, what are you afraid that you will discover? You are perfectly free to put on the blinders, but to what purpose?

> Subcomponents of the current may be useful for handwaving explanations,
> but they are not superior to the standard net current model.

Is the "standard net current model" so perfect that it will never be modified? Please think outside of the box on this one, Gene. You are essentially saying that all the human knowledge that has been accumulated on this subject is all that will ever be discovered. That reminds me of the patent clerk who, around 1900, declared that the patent office should be closed because all possible discoveries had already been made.

> Any
> modeling results must agree with the standard model (widely used for
> more than 100 years) or else the simple handwaving model is likely to be
> bogus.

Can you prove that the "standard model" is perfect? If not, is there a chance that it is not perfect? Are you opposed to discovering imperfections in the "standard model"? Do you have the cahones to defend the standard model in a rational technical discussion?

> Soooo, we are back to the beginning.

No, we are back to your EM metaphysics. I am begging you, Gene, please, please, allow yourself to think outside of the box. What do you have

to lose except your religious-like beliefs? If your beliefs are correct,
it should be relatively easy to prove me wrong. If your beliefs are
incorrect, don't you want to change them? What, exactly, are you afraid of?

The mere fact that you resort to an argumentum ad verecundiam (diversionary
appeal to authority) argument tells me that you are afraid to consider
anything new.

So are you going to sandbag behind an omniscience flag, or are you going
to engage in a rational technical discussion where the outcome is unknown?

I am not trying to be difficult. In a one-on-one discussion, I will
either be proven right or wrong. I'm not afraid of that - are you?

The technical information published on this particular subject is
non-existent. Therefore, there is nothing published that contradicts
what I am saying. Why do you think that gives you an advantage?

>
> Somehow I expected this.

I didn't mean to imply that I don't know the equations - I do. I just
don't know the value of all the constants in the equations.

Given that a horizontal dipole 24 ft. above ground and constructed from
#16 wire will have a natural Z0 of 600 ohms:

The forward current will be an If-max value multiplied by an exponential
relating to frequency multiplied by an exponential relating to the loss
of energy due to conductor resistance and radiation.

The reflected current will be an Ir-max value multiplied by the same
exponential relating to frequency multiplied by the same exponential
relating to the loss of energy due to conductor resistance and radiation.

We know that (Vf+Vr)/(If+Ir) equals 50 ohms for a dipole whose feedpoint
impedance is 50 ohms. With a 1/2WL dipole the current equation is clear.

Here is the equation you asked for, unfortunately in ASCII:

Itot = If-max*e^-yz*e^-2az + Ir-max*e^+yz*e^-2az

same as it is for a transmission line. The I^2*R losses plus the
radiation "losses" are combined into the attenuation factor 'a'.

So I can indeed write you an equation for a wire dipole. The coil
in the mobile antenna causes another level of complication, and
that is the equation with which I am struggling at the moment.
In addition, the vertical nature of a mobile antenna means that
the Z0 is changing with length. That is a minor problem compared
to including the reflections from both ends of a loading coil in
both directions. But I have no doubt that I can solve that problem.

True. Although it's worth noting that the traveling waves, or
subcomponenets as you call them, are actually the source of radiation.
The fields generated by forward and reverse waves of course superpose to
produce the net field. Obviously in practice it's considerably simpler
to just superpose the currents in order to obtain the net field, but the
result should be the same either way.

I have a question. If a loading coil only makes a physically short
antenna look like it's an electrical quarter wavelength reactively, why
does its position along the radiator make such an apparent difference in
performance?

> NOTE: Lessons Learned.

I've tried a few coax loops, and I guess they are ok, but in general, I prefer the normal solenoid windings using plain wire... Much lighter, and the performance *if properly balanced* , is the same. I only use variable caps to tune the loop. My present loop that I use the most is a diamond, appx 44 inches per side, and has 5 turns. "The PVC frame is about 6 ft tall, counting the mast below the loop winding, and the cross arm is 5 ft across" I use a multi gang variable for tuning, and it has a switch to change to a small value gang for upper freq range use. Also have some fixed caps to tack on if I want to listen to LF. With all the cap variations, the tuning range is about 250kc to about 2500 kc or so. But it's usually used on MW and 160m. It's indoors on a stand thats next to me on the floor and rotates...MK

No, that isn't the equation I asked for. Nowhere in your equation are L1, L2, L3, L, I, or F. Whatever your equation is supposedly solving for, it isn't what I asked.

I feel strongly that if you really understand what you're talking about, you should be able to express it mathematically as an equation or equations. I haven't seen any evidence of this.

How long are your radials, and where are the? If you used four 11 foot radials, and drooped them down about 45 degrees, the antenna should look like 50 Ohms somewhere around 21.2 MHz. Is the SWR better at the high or low end of the band, i.e. 21.0 or 21.4 ? Coax is 50 Ohms, right. You might want to look in some charts to see how much effect the fat 3/4 conductor is going to make, as opposed to wire.

Richard,
It was ten years ago that this subject came up and which I used as a basis for
parallel circuit antennas versus series type antennas. It also led to the use of
circuitry analysis (complex circuitry) to provide for lossless feed systems and
cluster coupled antennas.
All of the above was ridiculed by the experts over the years because of my use of element coupling terminology, such that what it
pertained to was never taken seriously and sometimes mocked.
What is more frausterating to me is that many commercial antennas still pursue
gain to the extent that low impedance occurs and where the purchaser is forced
to purchase loss generating matching systems which robs him of some of the purchased gain. Force1 even notes in their literature that manufactures are supplying
poor matching impedances in the search of financial competitive gain
YOU are the first expert on this newsgroup to take a step back and pursued a
rethink of this subject and supplied your findings in a posting.
Possibly some will now subject you to ridicule or,
if your enunciation of Terman is convincing enough, will say they knew it all the
time but preferred to pursue harassement.
I thank you from the bottom of my heart for your courage shown in your last posting
and hopefully, others will build on, or pursue the implications/contents of your posting.
Best regards
Art KB9MZ Xg

Ummmm, look: Here is why answering an open ended question like yours is essentially impossible.

Who has a large financial interest in reaching an answer to this exact question? FM broadcast stations, that's who.
For transmitting. But, there remain about a half-dozen manufacturers still in that business, competing, and if one were
"The Best", then the others would quickly disappear from the business. For example, Andrew, Dielectric, Jampro,
Shively, and Superior are all still in business, AFIK, but are likely too pricey for your requirement. I happen to
prefer the Jampro myself. And Richard Harrison may have newer catalogs than I have at the moment.

And, when you put the unrealistic 1 meter dimensional restriction on it, then this "Best" description fails totally.

I took a quick look at the ARRL antenna book. Assuming your 3/4 pipe is actually 1" OD, resonance will be off by quite a bit. About 6 - 7 inches too long.

Who here remembers Bob Cooper and CATJ magazine from 25 years ago?

There was a fellow in the UK who was doing exactly what you ask, but I can't remember his name. He wrote a column in
CATJ describing his work. I don't recall what size dish he used, but I am sure it was no larger than 10 meters, as he
had limited resources and space.

On the other hand, national governments routinely do what you are describing, using 50 to 100 meter dishes, even the 200
meter one in West Virginia before it collapsed.

> equations. I haven't seen any evidence of this.

Well, You're right. I should be able to express it as an equation. Truth is, personality wise, I tend to deal in concepts, not equations. That's why the field of digital electronics was so appealing to me. "If it's not a zero or a one, it's broke!" I seem to have been born with a Boolean Algebra processor built in. (It's similar to the fact that I can read Spanish but I can't speak it.)

I have been satisfied all my life to let someone else provide the equations and so far, I have been able to stand on the shoulders of giants. But in this case, if anyone has ever provided the equations, I am not aware of it. If one is so inclined, one might get to be famous by generating those equations.

The S-parameter equations should work just fine at each individual impedance discontinuity. The trick is in knowing how much to reduce the incident and reflected voltages because of radiation. It's one approach to think about.

One possible solution would be to model the antenna as a transmission line, as Balanis and Kraus suggest. If we made a 1/4WL open-circuit stub out of resistance wire with Z0=600 ohms such that it's feedpoint impedance is 50 ohms, it should be a good approximation to an antenna wire.

In any case, the loading coil has a steady-state forward current (If) and reflected current (Ib) each of which undergo a phase shift through the coil. Any phase shift in phasors traveling in opposite directions is cause for their sums to be different at each end of the coil. I'm surprised that such a concept is controversial. Exactly the same concept applies to 'X' degrees of a transmission line with reflections.

> By far, the most sensible statement yet made in these interminable 'coil'
> threads.

Well, I have already posted the equations. During steady-state, there will be some magnitude of forward current (If) through the coil and some magnitude of reflected current (Ib) flowing backwards through the coil caused by reflections from the tip of the standing-wave antenna. The net current at any position up and down the antenna is Ir+Ib. That's a pretty simple equation. Since there is a phase shift in Ir and Ib through the large bugcatcher coil, the sum of Ir and Ib will not be the same at each end.

In an electrical 1/4WL antenna, like a typical 75m mobile antenna with no top hat, the If+Ib sum at the bottom will always be a larger magnitude than the If+Ib sum at the top. Modeling the coil as an eight-sided helix in EZNEC resulted in:

http://www.qsl.net/w5dxp/octcoil.gif

The net current at the bottom of the coil is obviously of a greater magnitude than the net current at the top of the coil. That's because If and Ib at the bottom of the coil are nearly in phase. Ir and Ib are about 58 degrees different in phase at the top of the coil. That tells me that the coil causes about a 29 degree phase shift when either Ir or Ib flows through it. It's not that simple but let's stick with simple for right now.

Thank you Greg. I guess these are the only available options that meet
my "specifications" (omnidirectional, can fit my attic).

Between these two, do you happen to know (or have an opinion) which one
is better?

Thanks,
Lynn

George, thank you for this very informative answer. I was completely unaware of these companies and I can now try to perform a Google search - if only to satisfy my curiosity (if the antennas are too expensive, then perhaps I am not interested in the "best").

As for the "unrealistic 1 meter dimensional restriction", you are right. I actually meant "the best omnidirectional FM antenna within that 1 meter size restriction". Also, if I am lucky I may be able to fit even the Winegard PR-6010 (67" or 1.7m wide) in my attic.

BTW, what do you think of a wide 25-1300 MHz Discone antenna as an FM/VHF/UHF omnidirectional antenna (http://tinyurl.com/4anu7). Can this work? (assuming ghosting for TV is not a problem...)

If so, is there a solution to matching its 50 ohm impedance to the cable's 75 ohm?

Thanks,
Lynn

# 1444. Re: The "TRICK" to TV 'type' Coax Cable [Shielded] SWL Loop Antennas {RHF}

FO&A,

Connecting your TV 'type' Coax Cable [Shielded] SWL Loop Antenna
to your Table Top Shortwave Receiver or 'Portable' AM/FM/Shortwave
Radio.

Table Top Shortwave Receivers:
For "Receivers" with a SO-239 Jack for the External Antenna
you can use an "F" Jack to PL-259 Plug (SO-239 Adapter)
RadioShack Catalog # 278-258

'Portable' AM/FM/Shortwave Radios:
For "Radios" with a 1/8" Mono-Jack for the External Antenna
you can use an "F" Jack to 1/8" Plug (1/8" Mono-Jack Adapter)
RadioShack Catalog # 278-257

~ RHF
.
.

Perhaps it's your background as a manager that's in evidence here. I was one of the people that "concept" people like you "let" provide the equations. I have an apropos Doonesbury cartoon on my office wall:

Pointy-haired boss, pointing to simple graph labeled "Sales": "Sales are dropping like a rock."

Pointy-haired boss, pointing to a graph labeled "Future", with single upward line: "Our plan is to invent some sort of doohickey that everyone wants to buy."

Pointy-haired boss, to Dilbert: "The visionary leadership work is done. How long will your part take?"

At review time, the boss judged me on whether the "doohickey" worked according to specifications that he and some marketing people came up with in "concept" meetings. All I had to do was to understand the science, come up with the equations, develop new technology as required, create the device, and make it work -- all on a schedule and within a budget which were also dictated by the "visionaries". Just grunt work, not worthy of the visionary people who were doing more important things.

I don't believe for a minute that the boss really understood how the device worked. And for the same reason, I don't believe that you really understand the "concepts" you're promoting. Real science and engineering are done by understanding the basic concepts, developing mathematical models of them based on those understandings, then using those models to test the theory. Without the understanding and models, the theories can't be tested. Then all you have are smoke, mirrors, and hand waving. Instead of solid, testable evidence, you just about have to resort to diversion, evasion, misinterpretation, and the other tools of the politician and upper level manager. As important and richly rewarded as those skills are, it isn't science and it isn't engineering, and it doesn't constitute evidence of any knowledge or understanding.

You seem to have convinced a few readers of the group that you know what you're talking about. Since you're apparently not able to express your ideas in concrete form, perhaps one of them will volunteer to do the mundane work of developing a coherent theory to explain it in scientific and mathematical terms. My only question to them is:

How long will your part take?

Well, no you haven't. Why do you keep saying that? I asked a simple question, and instead of answering it, you've answered some other question that you prefer, then claim it's the answer to the question I asked.

I took only one political science course in college, and that was the technique used by the majority of students. It's also the universal technique of political candidates. I'm asking techical and engineering questions, and you're giving political answers. No wonder we don't communicate.

This isn't a game I like to play and, since leaving the cube farm, it's one that I no longer have to. So I'll bow out again and leave it to the folks who do enjoy this form of discourse.

Taking a look at just the loading coil, the math is very simple.
Since a loaded mobile antenna is a standing wave antenna, there
exists a forward current through the coil. Balanis labels that
current as 'If'. There also exists a reflected current flowing
backwards through the coil. Balanis labels that current as 'Ib'.
The current at any point in the coil is the superposed sum of
If + Ib. The net current within the coil is approximately a section
of a cosine function.

On my web page is a mobile antenna modeled with EZNEC using a
segmented octal shaped coil.

http://www.qsl.net/w5dxp/octcoil.gif

EZNEC reports that the current at the bottom of the coil is
0.9956 amps and the current at the top of the coil is 0.5326.
Assuming the current is approximately a cosine function through
the coil, the approximate number of degrees occupied by the coil is:

arccos(0.5326/0.9956) = ~58 degrees

The other eight feet of antenna is equal to about 42 degrees
at 13.5 MHz.

58 + 42 = 100 degrees is within 10% of being 90 degrees and
seems reasonable for a ballpark estimate. This seems to be
a clue that a loaded mobile antenna is electrically slightly
longer than 90 degrees.

The forward current and reflected current magnitudes through the
coil are probably within 90% of each other for a mobile antenna.
Kraus considers them to be equal for a dipole discussion
in his book. Considering them to be equal introduces a small error
but is good enough for a reasonable estimate.

The point is that the difference in the net current at each
end of a coil gives us a rough estimate of the number of electrical
degrees that the coil occupies in the antenna. The whip above the
coil can be considered as a load on the source energy at the top
of the coil. It is unlikely that the coil is capable of changing
the characteristics of the load which would be necessary if Tom
were right.

If the coil occupies zero degrees, as implied by Tom, W8JI, then
the other 8 feet of the antenna would have to occupy 90 degrees
to make the feedpoint impedance resistive. I would say that shoving
90 degrees into 8 feet of whip at 13.5 MHz is impossible. That 8
feet of antenna would have to have a velocity factor of 0.46 which
is unlikely. At 4 MHz, that 8 feet of antenna would have to have a
velocity factor of 0.137 to occupy 90 degrees. That's seems obviously
impossible. Tom's requirement that a wire change velocity factor with
frequency is really hard to accept.

You must have missed some of my postings. I have already expressed my
ideas in concrete form. Maybe you don't like the simplicity of

Itot = I+ + I- (I+ is forward current and I- is reflected current)

Standing wave antennas possess standing waves. Standing waves occur
when forward waves and reflected waves are superposed. The phase
rotation of these two component currents are in opposite directions.
The result is a sinusoidal function for both net voltage and net current.

Any real-world air-core coil has a phase delay that affects the forward
current and the reflected current. Since they are phase rotating in
opposite directions, the overall effect is doubled. It's all explained
on my web page. Have you taken time to read it?

>
> Well, no you haven't. Why do you keep saying that?

Because it's true. Here are the equations again.

A loading coil exists in a standing-wave antenna.
The forward current through the loading coil is I+.
The reflected current through the loading coil is I-.
The net current at any point in the coil is I+ + I- (phasor addition)
The magnitude of the net current depends upon the phase of I+ and I-.

Itot = I+ + I-

There's the equation that I have already posted many, many times.
Sorry you missed it.

A rough estimate of the net current at the top of a loading coil
can be had by estimating the number of degrees occupied by the
coil and assuming a net current cosine function through the coil.

I love the simplicity of Itot = I+ + I-. I also like the simplicity of 1 + 1 = 2, V = I/R, and e^(j*pi) = -1. But none of these is adequate to determine the current at the top and bottom of a loading coil.

Yes, and for the life of me I can't see how to use it to find the current at the top and bottom of a coil in a simple monopole.

But I'm kind of dense. Can one of the many other readers of this group kindly explain how Cecil's equations and explanations are used to actually figure out what the current will be at the top and bottom of a loading coil? Yuri, you seem to understand it -- can you explain it to me? Richard? Surely the necessary equations are in one of your books?

Is it ground mounted? And what kind of radial are in use (if any).

Does resonate in your terms mean that you have a low swr?

Hi John,

You didn't say, but I assume that you are feeding it against several quarter wave radials at or near ground level. You will get a feed impedance of less than 50 ohms, so you will need some matching to get a 1:1 swr. You need to concentrate on getting resonance irrespective of swr and then match the anteena feed for minimum swr. This can be done quite simply by putting a capacitor, usually silver mica, across the coax at the feed point, or by inserting a transformer between the coax and the antenna to match something like 10 to 20 ohms to the 50 ohm feed. The capacitor is the easiest to try first, and you will probably need something between 50 and 100 pf.

I hope you find this useful, and I wish you success. 73, Jack. G3PVG.

I will leave Cecil's equation to Cecil, but I will point out that you can use your own creation EZNEC 4+ and HELIX feature to model the quarter wave vertical with loading coil. I did it after your pointed out HELIX feature and posted it at the beginning of my thread, here it is again, actually using "worst" case of 10m loaded whip (not too much loading) and demonstrating significantly different (not equal) currents at coil's ends. Did I do anything wrong?

Here it is again:
<<
I took the time to check out the Helix feature in EZNEC 4.08 and modeled the "worst" case - CB whip or 10 m whip with loading coil - helix half way up and then the same helix moved up to 3/4 way up. Things will get more pronounced when more turn, more inductance coil is used and frequencies are lower. Yes, Virginia there is a CURRENT DROP across the loading coil, unless you have more "appropriate" or "scientwific" term for it.

Rough dimensions: 1m mast (5 mm copper wire/tubing), 20 cm long coil/helix with 5 cm diameter turns, 5mm wire diameter, 10 turns, spacing 2 cm followed by 1 m whip
Resonated at 27.05 MHz
With base current 1 A, at the end of mast/start of coil the current is 0.87457 A
at the end of coil/start of whip the current is 0.66884 A - a decent drop of 0.20573 A or 20.5 % - not an "EQUAL" (you DC coil believer types!!!)

Then I moved the same coil up 50 cm, so the mast was 1.5 m, same coil, followed by .5 m of whip.
Again with base current of 1 A, the bottom of the coil had current this time was 0.65479 A, while top of the coil 0.37127 with larger drop of 0.28352 A or 28.3 % - even bigger not "EQUAL" with resonant frequency moving up to 28.7 MHz, which corresponds to REALITY measured, experienced and finally properly (close enough) modeled. Even M0RON (with apologies if there is call like that issued :-) can see the nice current drop across the coil displayed in the VIEW.

Thank you Roy (now you believe it?), Cecil, Richard. Now the unbelievers can even model this case themselves and SEE it properly. So ON4UN, K3BU, W9UCW,

W5DXP, KB5WZI were and are right. W8JI, G3SEK et al are sooooo wrong :-) Some still persist, some are converted and many will be enlightened.

Now if Roy can incorporate elegant way of modeling real life coil/inductance by inputing Inductance L and its physical size and have it calculate things without modeling turns, that would be a winner and a segment saver.
>>

Not sure if you saw it, but it looks to me that even EZNEC 4+ is on "our" side.

>

My first reaction is to point out that this was (is?) a question on the Extra exam.
Now how can I explain qualitatively why this is?
Consider an end-fed wire antenna.
An electromagnetic wave goes through the conduction electrons down to the end and reflects back.
At 1/4 wavelength, the reflected wave is exactly in phase with the source so the load looks minimal and resistive, loss plus radiation. As the antenna gets shorter the radiation resistance gets lower and the reflected wave gets back to the feed point sooner (becomes capacitive). We need to add inductance to slow down the wave so it gets back in phase. We cannot, alas, raise the radiation resistance; this is a short antenna. If I place the inductor at the feed point all the current must flow through it, maximizing loss. If I place it at the top little current flows through it, minimizing effectiveness. If I distribute it the antenna's resonance is broader, but at what cost? Lower Q. The signal strength is less. So I make the coil as short as I can, put it in the middle and it's juuust right.

We don't have to determine the current at the top and bottom of a loading coil. All we have to determine is that the current at the top and bottom of a loading coil cannot be equal in magnitude. It's a simple true/false logic question, not a question of degree of accuracy.

EZNEC says the currents are not equal when the helix feature is used to simulate a real-world coil.

Your and Tom's measurements proved that the currents are not equal except for Tom's one special toroidal case where he probably located the current maximum point within the inductor.

> Yes, and for the life of me I can't see how to use it to find the
> current at the top and bottom of a coil in a simple monopole.

You don't have any equations either but that doesn't stop you from making assertions about those currents. Why are you attempting to hold me to a higher standard than you hold yourself or Tom? I'm not asserting anything new. I learned the qualitative basics of this subject at Texas A&M almost half a century ago. I'm amazed that those basics don't seem to be taught any more.

> But I'm kind of dense. Can one of the many other readers of this group

It is not necessary to figure out what the current will be. That is just diverting the issue. All that is necessary for the present argument is to show that, in the 90 electrical degrees of a mobile antenna, that the two component phasor currents at each end of the coil don't add up to the same value. I have done that.

Since the bugcatcher coil shifts the phase of both the forward current and reflected current by the same amount in opposite directions, it is impossible for the current to have the same magnitude at both ends of the coil when the loading coil is installed at the 45 degree (center-loaded) point in an electrical 1/4WL antenna.

Now where was that chapter in E&M about "superposition of currents"?
Can't seem to find it. There is stuff about electromagnetic FIELDS.
In CecilsWorld wires have an infinite number of conduction electrons.
Reminds me of BushWorld where there Iraq had nukular weapons and we have
internets and the Rapture is coming.
Soon.
Roy, why do you bother?

Simple rule, as mentioned in ON4UN book, the efficiency of the antenna is proportional to the area under the current curve. When you model the antenna and view the current distribution and compare various cases with coil positioned at bottom, middle, top, it is obvious why. It also shows why it is important to understand the role of the loading coil and its effect on the current distribution along the radiator. This effect gets magnified when using loaded elements in parasitic beam designs. If you use "zero" size inductance in modeling, the results are "too good" and correlation with reality is way off. That's what is all about.

The equation, Itot=Ifor+Iref, doesn't look complex, but it is. :-)

> Not sure if you saw it, but it looks to me that even EZNEC 4+ is on "our" side.

I modeled an eight-sided coil in EZNEC 2.0 before I knew EZNEC+
had a helical feature. The result is at:

http://www.qsl.net/w5dxp/octcoil.gif

EZNEC reports that the current at the top of the coil is 0.5326
amps while the current at the bottom of the coil is 0.9956 amps.
I plotted the current in all 40 EZNEC 2.0 coil segments - looks
close to a cosine function to me with the coil occupying
roughly 50 degrees of the antenna.

Exactly. The coil provides a delay and a phase shift. A series
stub will accomplish the same thing. In the middle of an
electrical 1/4WL antenna, any delay through the coil ensures
unequal net current at the bottom and top of the coil even
if the coil is lossless and non-radiating.

Lynn,,
Were I in your position I'd go with the Winegard Prostar 1000
referenced in an earlier post. That and the Antennacraft FMSS are

essentially the same so you may just want to choose between the two based on price. Radio Shack used to sell this antenna also, not in the current listings but perhaps a store near you has one left in 'old stock', their price was about $15 less the coax feedline. Forget the discone, it will work - though I can't say any better than the two antennas mentioned - but what you gain in reduced footprint is lost in the discone being taller. Also, you can expect to spend more for the discone.

FWIW, I put up the Radio Shack crossed dipole antenna at a friend's cabin and it took him from getting no FM reception to two stations. Okay, not an "FM DX antenna" but consider that he is 40 miles from any town of significance, the cabin is in a valley and there are taller mountains between him and anything else.

Good luck,
Howard

Yes, ground mounted and using 4 5-1/2ft radials. Bad word choice in
orig post-poor SWR is the problem. The other poster mentioned my pipe
diameter may be an issue. Am looking into that now.

Newsgroups: sci.electronics.design,alt.engineering.electrical,rec.radio.amateur.antenna
Subject: Re: Loop Antenna questions

It's fairly easy to see that what Tom wrote (the first paragraph of
quoted material below) is true. "Shielding" a loop simply moves the
feedpoint to the gap, and the outside of the "shield" becomes the loop.
It's no more or less immune to electric fields than any other loop. What
"shielding" does (and all it does) is to increase rejection of common
mode excitation, improving loop balance and the resulting pattern null
in practical installations. The sensitivity of a "shielded" loop to both
electric and magnetic fields is exactly the same as for an "unshielded"
loop.

The myth that "shielding" a loop somehow rejects the electric field
without affecting the magnetic field is one that's been kicking around
the amateur community for decades. I don't suppose it'll ever die.

Another thing that seems to be unknown or overlooked is that a small
(so-called "magnetic") loop antenna is actually more sensitive to an
electric field and less sensitive to a magnetic field than a short
("electric") dipole, at all distances from the antenna unless the
radiation source is very close -- within less than a wavelength.

Newsgroups: sci.electronics.design,alt.engineering.electrical,rec.radio.amateur.antenna
Subject: Re: Loop Antenna questions

After some reflection, I see that I can't really justify the statement I
made. Thanks for questioning it.

Let me explain what I do know. The following discussion assumes that all
antennas are lossless, to eliminate a factor that would obscure the
subject under discussion.

If you put 100 watts into a very short dipole, the ratio of the E field
it produces to the H field it produces is called the wave impedance. At
a distance of considerably less than a wavelength, or greater, this
ratio is about 377 ohms (in air or free space), and E and H are in
phase. The same thing is true for a very small loop antenna, or any
other small antenna. If you get far enough away, the E/H ratio is the
same for any kind of antenna, although you might have to get a farther
from an antenna that's large in terms of wavelength. Invoking the
reciprocity principle, you find that the relative response of a small
loop to E and H fields is the same as for a small dipole if the field
originates some distance from the antenna. The so-called "magnetic" loop
responds just the same as any other antenna to fields originating beyond
a wavelength or so from the antenna.

What's interesting is the relative strength of radiated E and H fields
close to the antenna. My overstatement was the implication that the
ratio of E to H transmitted fields represent relative "sensitivity" to E
and H fields when receiving. Contrary to what the CFA and EH proponents
claim, it's not possible to generate E and H fields independently. And
contrary to what people who misunderstand "shielded" loops say, it's not
possible to isolate E and H fields. (It is possible to change the
impedance of a wave -- that is, the E/H ratio -- in a region, but it

always reverts back to the impedance of the medium -- 377 ohms for free space -- within a pretty small distance of the disturbance.) So sensitivity to an E or H field is somewhat problematic, since you can't create either one in isolation for a test. Consequently, I'll just discuss the E and H fields that the antennas produce when transmitting. I believe that an antenna with high transmit E/H ratio will be relatively insensitive to a wave with low E/H ratio (which would have to be created nearby), and vice-versa. But I can't quantify the relationship. I only know it involves the concept of transfer impedance, and I haven't given the topic enough study to say more about it. It is discussed in a number of texts, for those who are interested.

What I've done is look at the E/H ratio radiated by a small loop and a small dipole at various distances, in the direction of the maximum far field radiation (in the plane of the loop and broadside to the dipole).

The following analysis was done with EZNEC/4 using its double precision NEC-4 calculating engine. This was necessary because of problems NEC codes have with very small loops, and the size of loop I chose was too small for analysis with NEC-2. However, it could probably be done with MININEC, or it could be done with an NEC-2 based program like the EZNEC demo if the loop is made a bit larger. It's vital to set the loss to zero so that a negative feed point impedance isn't concealed by positive loss resistance. I've gotten email from a person who was skeptical of the results and did the calculations analytically. He came to the same conclusion, which gives me added confidence in the results. The following calculations were done at 3 MHz (100 meter wavelength).

Here's what happens. A small loop is sometimes called a "low impedance" antenna because of the low E/H ratio close to the antenna. This might be adequate justification for calling it a "magnetic" antenna as amateurs have taken to doing, but the term unfortunately conveys the mistaken impression that the antenna somehow responds only to or more strongly to magnetic fields coming far from the antenna, which isn't true. But very close to the antenna, the E/H ratio is indeed lower than the 377 ohm value this ratio always has far from the antenna. In exactly complementary fashion, a small dipole is a "high impedance" antenna, having an E/H ratio higher than 377 ohms very close to the antenna. Here are the values of the magnitude of E/H for a 2 meter (1/50 wavelength) circumference octagonal loop and a 2 meter long dipole at 3 MHz. The distance is measured from the center of the loop or dipole, and the direction is in the plane of the loop or broadside to the dipole.

Distance (m) E/H (ohms)
Dipole Loop
2 2630 63.9
4 1360 110
6 862 169
8 597 241
10 440 326
12 345 414

14 291 490
16 265 538
18 257 555
20 258 552
22 264 538
24 273 522
26 281 506
28 290 491
30 297 478
50 342 415
100 367 386

The curious thing is that, while the dipole field impedance is high close to the dipole, and low close to the loop, in both cases it overshoots 377 ohms by a considerable amount, reaching a peak (lowest Z for the dipole and highest for the loop) at about 18 meters, then asymptotically approaches 377 ohms from the "wrong side" beyond that. At all distances of 12 meters (about 1/8 wavelength) and beyond, the E/H ratio of the loop is actually higher than that of the dipole! That was the basis for my original statement. Whatever might be said about the "sensitivity" of a "magnetic" loop to E and H fields, it certainly can't be said to be more sensitive to H fields, or less sensitive to E fields, than a small dipole, at any distance greater than about 1/8 wavelength.

The exact sizes of the loop and dipole aren't important. The near fields at these distances are essentially equal for all small dipoles and for all small loops for a given input power, provided that they're much smaller than a wavelength in any dimension.

> another figment of wish fulfillment).

My understanding of the CFA/EH antenna is undeniably vague, but I think it goes something like this: The E and H fields are created independently, one by a capacitor-like part of the antenna and the other by a coil-like part of the antenna. This, as I said and as many others have pointed out, can't be done. Creation of a time-varying E field always results in a time-varying H field, and vice-versa. The E and H fields thus "independently" created are done so in the ratio of 377 ohms. This being the ratio of the the components in the far field, the direct synthesis results in the lack of a near field. This lack of near field is credited somehow with the magical properties of these antennas (high efficiency despite small size) by mechanisms that have never been clear to me. At any rate, these wonderful properties have never been demonstrated with either believable measurements or modeling despite more than a decade of hype, so it sure looks like they're fiction also. The EH antenna further distinguishes itself by requiring a magic inductor whose current at one terminal is shifted in phase 90 degrees from the current at the other terminal, adding yet another layer of impossibility.

If I've misinterpreted the explanations for how these things are supposed to work, I apologize -- it wasn't intentional.

It might. Remember, though, that this is constant in terms of wavelength, so the range drops by a factor of two at twice the frequency. (But on the other hand, the range will be greater at 160 meters.) Also, note that the difference isn't very great even at a distance of 10 meters. You have to get very close indeed to see a truly major difference. I suspect that major differences in interference rejection are as likely to be due to differences in balance (causing better or worse nulls) or polarization.

> It seems to me that the difference applies only to situations where
> that first 10M is significant, and to what degree coupling of

Yes, that's the conclusion I reach.

wrote:
> can you explain it to me? Richard?

Hi Roy,

This Richard could with his books, but I doubt you meant me (that's
why the FCC assigns call signs).

So, given my toe-hold of ambiguity....

The explanation was offered by my posting quoting Poe:

"The error of our progenitors was quite analogous with that of the
wiseacre who fancies he must necessarily see an object the more
distinctly, the more closely he holds it to his eyes. They blinded
themselves, too, with the impalpable, titillating Scotch snuff of
detail; and thus the boasted facts of the Hog-ites were by no
means always facts -- a point of little importance but for the
assumption that they always were. The vital taint, however, in
Baconianism -- its most lamentable fount of error -- lay in its
tendency to throw power and consideration into the hands of merely
perceptive men -- of those inter-Tritonic minnows, the
microscopical savans -- the diggers and pedlers of minute facts,
for the most part in physical science -- facts all of which they
retailed at the same price upon the highway; their value
depending, it was supposed, simply upon the fact of their fact,
without reference to their applicability or inapplicability in the
development of those ultimate and only legitimate facts, called
Law."

Of course, this was encumbered by more commentary from Poe, and as
this group has such difficulty in reading English, then perhaps the
nuances were lost to the greater appreciation of what was being said.

I will hit the hi-lights:

The term "wiseacre" hasn't lost its currency over the course of 165
years, but I suppose many english (lower case) readers probably have
lost track of the meaning of "minute" to presume it is only a unit of
time.

"... the wiseacre who ... must necessarily see an object the more
distinctly, the more closely he holds it to his eyes. ... the
diggers and pedlers of minute facts, ... their value depending ...
simply upon the fact of their fact, without reference to their
applicability ..."

To translate this Classic Comix edition of Poe into techno-jargon:

"Current Drop" accounts for less than 1dB in the far field.

To boil it down further for those who parse only Anglo-Saxon

If I can fit it in my attic *and* eliminate the need to have two antennas (TV and FM), I am willing to spend the extra cost (up to $100).

I get most of the TV stations that I want through basic cable service. There are two local TV stations that I receive very well with a simple rabbit ear antenna (came with the TV), so my requirements from a TV antenna are not very high.

I guess the only questions I have regarding the discone antenna are:

1) Are there any issues in regard to wave polarization? Is it true that both TV and FM broadcasts are polarized both vertically and horizontally?

2) How does one match between that about 50 ohms antenna impedance and the cable's 75 ohm impedance?

Yes, that is exactly the kind of result I want to achieve. I know there is no magical solution that defies the laws of physics (50% signal loss when placed in the attic, size, etc.) such as the "bogus antennas" described here: http://www.kyes.com/antenna/antennatypes/antennatypes.html

Roy, you asked for a couple of simple equations which give the currents
at the two ends of the coil. Here they are again:

Itot(bottom) = I+(bottom) + I-(bottom)

Itot(top) = I+(top) + I-(top)

Exactly what equations do you use when you make your assertions about the
current at each end of a coil? Please be specific.

Hi H.,
this is interesting in a sick sort of way. You've got Cecil,
a cloud cuckoo land philosopher espousing his inchoate, hand waving
"theory," Yuri, the consummate empiric, who thinks he can understand
nature by experiment alone, and Richard Harrison, who understands the
natural world almost solely through the agency of written authority; and
all of these erstwhile fellows together can't get it right.
We're all marching in lockstep right back to the middle ages.

> 73, H. NQ5H

Sounds like you're describing a sort of 'current drop'. Is I^2R loss entirely responsible for this drop? It seems that the phase shift you described earlier would have to cause a change in the standing wave pattern along the radiator. If the loading coil was at the feedpoint, then the maximum current would appear only at the feedpoint. Above the coil, the currents would be out of phase, as you described, because of the shortened radiator, and the maximum available current would not flow along any point on the radiator. Moving the coil higher would allow maximum current to flow along at least the lower portion of the radiator. Loss is certainly a factor, but I can't see how it is the entire explanation for the rather pronounced effect. Hence my question.

I have the 19th edition. There is a graph on page 2 - 5. Kind of rough, but
I got k=.95 for 1" conductor at 21.3 MHz, which makes the real resonance
21.3x.95=20.235. I did not read the text, but they may give an equation
also.
If the SWR is lower at 21.0 than 21.4, the radiator is too long.

First change the radials to 11 feet, and then see what happens. Your SWR at
resonance should be 1.5:1.

Lynn -

This really gets to the heart of your design and selection question. From your location you need to determine the bearings 0 to 359 (with North at 0/360 and E at 90 degrees), where the FM (or TV stations) transmitting antennas are. Geography and population density usually "clump" these large transmitting towers in a small area. (Chicago - Sears and Hancock skyscrapers; New York - Empire State Building and Palisades (NJ))

The layout of these transmitting antennas in a 60 mile radius will help you select the ideal antenna pattern for your location. Instead of an omni, you may be able to use a beam, if all of the stations (that you really wish to listen to) are in a 30 degree or less spread.

Jon -

One of the old ARRL Antenna Handbooks (Green cover - circa 1973) had a 15 meter dipole constructed form 2 piece of 1/2 inch 10' electrical conduit and a small coil wound from 1/8" copper or brass tubing (50 ohm coax fed).

The impedance for a vertical will be quite low (less than 50 ohms) what are you using for matching?

15 meters / 4 = 3.75 meters (1/4 wave) ~ 12.3 Feet

Source record: 87373

Cecil,

I decided to take a look at the question you asked below, and I came up with a really simple modeling experiment.

Set up a simple quarter-wave vertical in EZNEC, resonant at 7 MHz. Run the source and current functions and save the data. Now change the frequency to 3.5 MHz and repeat the source and current functions. Do not scale the antenna or change anything else. I believe most people would now view this antenna as one-eighth wave at the new frequency, or perhaps representative of a whip above a loading coil (at 3.5 MHz).

This experiment demonstrates what happens to the "remaining eight feet" when confronted with the conflict between the "need" for 90 degrees and the availability of only 45 degrees.

My computer did not blow up, and I suspect yours will survive as well.

Any number of permutations can be tried. Change the length instead of the frequency, scale up, scale down, and so on. The current always starts at 1.0, and it always goes to 0.0 at the tip. The reactance and driving voltage can be awesome, but the current remained unfazed (or is that unphased?).

This is not a revelation. Antenna books point out that the current in a short antenna decreases in a straight line, not a sine curve, from the feed point to the tip. (E.g. Kraus, 2nd Ed. page 216)

Since your traveling wave model seems to be based on a 90 degree requirement, you may want to consider incorporating this additional information before submitting your new model for publication.

73,
Gene
W4SZ

(The "eight feet" is taken from your message. In this experiment the whip length is quite a bit larger, of course. Rescale the entire experiment if you like.)

Isn't that simply because the slope of a sine wave near the zero
crossing closely approximates that of a straight line?

I just acquired a Wilson 1000 base-loaded mag-mount antenna. The whip is 62" long and gives lowest SWR (1.2) at CB channel 1 (26.965 mHz). So, to be a good CB antenna, the whip needs to be shortened to give lowest SWR at 27.200 mHz -- roughly the middle of the CB band.

I want to also use this antenna for 10M. I don't want to bother with a tuner. I originally was going to buy a second, even shorter, whip for 10M and switch the whips for th eband I wanted at the moment. Then I thought that maybe I could throw together a simple RLC circuit to use at the radio for 10M.

How can I determine what I need? I think I have more than enough sophisticated equipment, but not the practical experience to use it.

In particular, I just built the AmQRP Antenna Analyzer and can measure the SWR, impedance and reactance at any frequency. I have a dip meter. I have manual tuners that can bring the SWR down to 1.0 in the middle of the 10M band.

How do I use these to design a simple RLC circuit that does what the manual tuner does at the middle of 10M?

I just finished re-directing my TV antenna in the attic to some favorite stations and boy it looks fabulous. :-)

However, I came across a very interesting phenomenon to which I have no explanation: if I install the two "Top Wing Boom" elements that come with the antenna, I get significantly worse reception. If I removed them (as the situation is now), I get close to perfect reception.

Is there an explanation to this?

The antenna is a Radio Shack VU-90XR VHF/UHF/ FM Antenna 150-2152.
Overview: http://tinyurl.com/52tjr

Daniel,
The "wing boom" elements form a corner reflector for the UHF section
of the antenna, in essence they make it more directional. Do you
notice this on UHF channels or VHF? If on UHF it is an indication
that the transmitter is not along the same azimuth the antenna is
pointing. Beyond that, it could be one, or a combination of, a few
different things. I know, not much help but at least you now know the
function those elements serve.
Howard

Art Unwin wrote:
"My ARRL books go back a decade or more and the graphs showing the gain per boom length has several curves based on different measurements e.t.c."

I haven`t encountered similar curves based on NEC, but I`ve found thye old ARRL curves on page 163 of my 1970 edition of the "A.R.R.L. Antenna Book" (cover price=$2.50).

Variation between curves from 3 different groups of observers are within "1 S-unit" (6 dB). Gain ranges from a minimum of about 7 dB for a Yagi with a 1/2-wave boom length (pessimistic) to a 19 dB gain for a 6.5-wavelength boom length (optimistic).

The optimistic curve is labeled "Greenblum", and seems too good to be true. The other two curves have flattened out as the number of wavelengths increases. The Greenblum curve is almost a straight line. As Kraus showed in his solution to the Deutsche Welle antenna gain problem, you often need to double the total number of elements to get a 3 dB antenna gain.

Best regards, Richard Harrison, KB5WZI

>manual tuner does at the middle of 10M?

Hi Ken, If you have the equipment to determine the impedance of the antenna at the middle of the 10M band, there are a number of ways to match it to 50 ohms.

First of all, you don't want an RLC circuit. Leave out the R cause that is power lost as heat. You want everything to be radiated. An "L" network consisting of an inductor and capacitor will match anything to anything.
What I usually do is determine the feedpoint impedance of the antenna at the frequency of interest, and use the Smith Chart to determine the configuration and values of an "L" network to get a match.
If you are not comfortable with the Chart, there are some programs on the net that will design the network for you. Or, if you give me the complex impedance and frequency, I will be glad to provide a network.

GG,

Interesting Information, Thank You for the Repost.

Somewhere, I remember reading that a Coax Cable [Shielded] Loop
Antenna is simply an End-Fed Dipole that is Terminated on Itself.
The fact that it is a Dipole (Electrically Balanced) and the Loop
Shape (Physically Balanced) give it it's inherent properties.

> the availability of only 45 degrees.

Once again, you misunderstand what I am saying which is: For an unloaded vertical antenna to have a purely resistive feedpoint impedance, i.e. resonant, it must be at least 1/4WL long fed against a counterpoise. A 45 degree unloaded antenna does NOT have a purely resistive feedpoint impedance, i.e. it is NOT resonant. We are discussing only resonant antennas here. A properly loaded short mobile antenna does indeed have a purely resistive feedpoint impedance, i.e. at resonance, it must exhibit something in the ballpark of 90 degrees of antenna. Hint: There is 90 degrees between the purely resistive current maximum point and the open end of the antenna. The coil MUST occupy some of that 90 degrees.

I'm not saying the coil occupies every degree not occupied by the wires but it does NOT occupy zero degrees. The argument is whether it occupies zero degrees or not.

Please stop misunderstanding what I am saying. :-)

> My computer did not blow up, and I suspect yours will survive as well.

Since you misunderstood, the rest of your posting is proceeding under false premises.

It does and that is why it is so difficult to write an equation for
it. There are reflections in both directions at the top and bottom of
the coil in addition to the 100% reflection at the tip of the antenna.
My solution is to get Reg to write a new program. :-)

> If the loading coil was at the feedpoint,
> then the maximum current would appear only at the feedpoint.

I hesitate to introduce secondary effects before most have understood
the primary effects, but that is not a true statement. Some percentage
of what the other side is saying is true. However, the other side
considers those effects to be supreme when they are only secondary -
but they are NOT negligible secondary effects. The maximum current
in the base-loaded system does not appear at the feedpoint. The
maximum current in a base-loaded system appears inside the coil and
that current is of greater magnitude than the feedpoint current. I'm
sorry to muddy the waters even farther with that tidbit.

>
> 73, Jim AC6XG
>
Hi Jim
Clearly an entire explanation would require a rigorous solution to Maxwell's
equations, but you state it better than I did.
The current below the loading coil is as if the antenna were full length,
max power radiated; the voltage above the loading coil is as if the antenna
were full length. And you're right, moving the coil away from the current
max (feed point) reduces I^2R losses in the coil. Are there E^2/R losses in
the coil if we mount it at the top?
Looks like if we make the boundary conditions at the ends of the antenna as
if it were full-length it works best.
Remember the boundary conditions; the current is max at the feedpoint and
zero at the end (can't go anywhere).
The empirical fact is a lumped L in the center of the antenna works best and
one can "sort of" intuitively see why placing the coil at either end has
problems. Hence I use a 4 foot screwdriver and a 4 foot whip. The antenna at
resonance on 40 and 80 is about 20 ohms which I match with a toroidal
autoformer. Then 2 feet of coax to the TS480HX.

Actually, no one really knows whether it's really a sine curve
or not because no one has ever been able to solve the integral
equation that would give an exact answer. The sine approximation
works o.k. because the far field is relatively insensitive to
changes in the shape of the current curve back at the antenna.
The best thing to do is to approximate the curve with a
moment method program on a computer. That's what the moment
method does best.

# 1496. Re: Gain per unit length of boom

Newsgroup: rec.radio.amateur.antenna
Date: 2004-10-29 00:32:12 UTC
From: "aunwin@insightbb.com"
Message-ID: <fcggd.265159$wV.97446@attbi_s54>
Source record: 87391

Richard, the more I study the boom length question the more I feel that the
ARRL
should drop the three curve gain/boom length graph. First there has to be a
condition that all elements are on the same plane. The other condition must
be
that all the elements are straight and parallel. The more I study the two
element
antenna I find that changing the added element height relative to one
another ,
even if a small distance , can change the gain.
I understand that there are "Landorfer ?"curved elements that can also
increase the gain.
I also proved that by NEC.
If one allows elements numbers to be added to increase ad hoc then NEC shows
that a quasi dish shape will occur
where the focus can stay equal to .1 wavelength and where gain increases to
over 14 dbi.
If one takes a further step by "shaping "the elements whether it be the feed
element or the
reflective elements then not only does the beam width narrow with increased
gain but the
TAO decreases about one degree which is a huge advantage when using small
garden type antennas.
Based on the above findings it would be impossible to generate a NEC curve
that would make sense
unless the above two conditions are set in place for the average amateur.
The latter would give
some protection against fraudulent vendors and supply a datum curve that is
meaningful to all.
I do believe that this posting should put an end to this thread and I thank
you again for your input.
Regards
Art

# 1497. New Smith Chart Program - "SmartSmith"

Newsgroup: rec.radio.amateur.antenna
Date: 2004-10-29 02:31:10 UTC
From: w9dmk@crosslink.net
Message-ID: <4181a8d7.50504291@news.crosslink.net>
Source record: 87392

SmartSmith for Windows is a Smith Chart program designed to provide a convenient tool for designing transmission line matching sections. It can also design matching sections for any electrical circuit in which it is important to be able to visualize the progress being made while configuring a particular matching section circuit element.

The program provides for data entry in the form of a complex impedance in "a + jb" (Cartesian) form that is to be matched to a purely resistive characteristic impedance as would typically be encountered in transmission lines. The primary limitation of such an approach for anything other than transmission lines is that the characteristic impedance of the line to which we desire a match is assumed to be purely resistive (no imaginary component).

SmartSmith for Windows provides the user with a suite of nine different impedance transforming elements that can be used in the program to implement an impedance match. These nine individually configurable elements are:

- Series Resistance (ohms)
- Shunt Conductance (milli-mhos)
- Series Capacitance (ohms of reactance and pF)
- Shunt Capacitive Susceptance (milli-Siemens )
- Series Inductance (ohms of reactance and uH)
- Shunt Inductive Susceptance (milli-Siemens)
- Open Stub (0 - 90 degrees, any Zo)
- Shorted Stub (90 - 0 degrees, any Zo)
- Series Trans. Line (-180 to 0 to +180 degrees, any Zo)

SmartSmith has many advantages over the paper Smith Chart. Plotting impedance points on a Smith Chart can be very tedious. Each time a new value of a design element is to be evaluated, the designer must generate a new value of reactance in ohms for that element and must then calculate a new value for the net impedance seen looking into the circuit with this new value of matching section in place. The designer then takes those new values of the real and imaginary parts, normalizes those values and locates the correct coordinates on the Smith Chart and draws a new point on the chart.

With SmartSmith that process is reduced to clicking the mouse on the spin control to change the value of that design element and see the new point being plotted instantaneously. SmartSmith also continuously shows the complex values of normalized admittance and impedance as the points are plotted.

In order to progress through the design steps, as a design element is completed, the designer presses the ?Keep and Continue? button in order to take the latest value of impedance and save that as the new Load impedance, leaving the plotted points on the Smith Chart. He then picks the next matching section type and begins configuring that element to continue the design, as necessary. At any point, the designer can use the ?Discard and Start Over? button to reset the system to the last ?Keep and Continue? values and select a different type matching section.

The most important feature of SmartSmith is its Wizard. Having entered the Load impedance into the program, the inexperienced designer may not have any idea where to begin. By pressing the ?What Would the Wizard Advise? button, the user is taken through a set of simple steps to transform that impedance to 1 + j0, normalized, and those steps have been automatically chosen based on the region of the Smith Chart in which the Load impedance is located.

> were full length.

That's semi-close but not entirely true. As Tom and Roy say, the coil indeed does distort the current away from the cosine pattern common in 1/4WL wire antennas. It just doesn't distort the current as much as they say. But the current at the top of the coil is a greater magnitude than it would be if your above statement were true. In one case, it is 66% higher than in a wire antenna.

The current at the top of the coil is greater than it would be for the same stinger mounted on a physical 1/4WL antenna but it is not equal to the current at the bottom of the coil. The coil probably causes a larger phase angle between the voltage and current than exists in a wire antenna. If theta is small, V*I*cos(theta) can be fixed while V and I become larger than they are in a wire antenna. There's a lot happening around that coil.

> Remember the boundary conditions; the current is max at the feedpoint and
> zero at the end (can't go anywhere).

Sorry, the current is not max at the feedpoint. There is a current maximum point located inside the coil that is a greater magnitude than the feedpoint current. If we say there is 90 degrees from current max inside the coil to the tip of the antenna, a center-loaded mobile antenna is longer than 90 degrees. One in particular, calculates out to be 110 degrees long.

The coil causes an impedance discontinuity at each end in the standing-wave antenna. It is somewhat like the following where the 10k ohm feedline represents the coil with a Z0=SQRT(L/C):

---600 ohm feedline---+---10k ohm feedline---+---600 ohm feedline---open

One can see that there would be reflections in both directions at the '+' points. That's why there will probably never be an equation to represent a mobile antenna.

Here's the key. (Vfor+Vref) must be in phase with (Ifor+Iref) at the feedpoint for the feedpoint impedance to be purely resistive. But Vfor doesn't necessarily have to be in phase with Ifor for that to happen. Neither does Vref necessarily have to be in phase with Iref for that to happen. The coil has a different phase effect on voltage than it does on current and the natural Z0 of a vertical antenna is not fixed since every point on the antenna is a different distance from ground. It's probably impossible to quantify using equations.

Tom Donaly wrote:
> Actually, no one really knows whether it's really a sine curve
> or not because no one has ever been able to solve the integral
> equation that would give an exact answer.

It would only be a sine curve if the reflected current was equal
to the forward current, i.e. the antenna was lossless (no I^2*R losses
and no radiation). We know that the reflected current is roughly about
90% of the value of the forward current at the feedpoint of a dipole.
So the total current distribution approximates a cosine wave. In the
textbooks you will find general assumption statements like Kraus':

"IT IS GENERALLY ASSUMED that the current distribution of an infinitesimally
thin antenna is sinusoidal, and that the phase is constant over a 1/2WL
interval, changing abruptly by 180 degrees between intervals."

For all real-world current waves, there is an attenuation factor. The
reflected current arriving back at the feedpoint is always less than
the forward current. That's why the feedpoint impedance,
(Vfor+Vref)/(Ifor+Iref) is low but never zero for a dipole. The net
current cosine function is a ballpark assumption, not actual reality.

This is interesting because (Vfor+Vref)/(Ifor+Iref) is 75 ohms for a
1/2WL dipole but is about 12 ohms for a 75m bugcatcher. That means
the reflected waves are closer in magnitude to the forward waves
in the 75m bugcatcher than they are for a 1/2WL dipole. That makes
sense since the tip of the antenna is closer to the feedpoint for
the 75m bugcatcher than for the 1/2WL dipole.

Message-ID: <2df3o01srhq7ppmevg1errb6k47jbd2mld@4ax.com>
Source record: 87396

I am trying to see if I can use some surplus 1/2 inch hardline
"feeder" for my 2m ssb loops and 440 sat antenna.
So far I can use my ssb loops from 144 to 145.4 under 2 to 1 swr.
And again from 146.5 to 148 as well. Keeping the Resistance at about
50 Ohms. The antenna SWR is 1.7 to 1 without the hardline.

Anyone else using CATV hardline for above HF freq.

W2RAC

It is a good example of why I do not read rec.radio.amateur.antenna.
Anything you read in it has about a 50% chance of being correct. It is
up to you to figure out which is right. If I want to read a thesis, I'll
crack a textbook where I stand a better chance of not being misled. With
technical articles, I also do not have to deal with terms like, myth,
oldwives tails, or requests for citations and the like.

Ummmm wouldn't it be easier to just trim the whip? Years ago I trimmed a 4 ft "Ugly Stick" down for 10 meters it worked quite well. I used to easily work Japan from my pickup in Portland Oregon with 25 watts, using just that ugly stick.

Technically, an Extended Double Zepp is a single-band antenna. That
76 ft. antenna is an EDZ on 15.8 MHz. An EDZ is 1.28WL, the point of
maximum gain for a dipole pattern. Below 15.8 MHz, the radiation pattern
will have two main lobes. Above 15.8 MHz, the radiation pattern will
become multi-lobed (cloverleaf) and have very little broadside radiation.
On 6.2 MHz, that antenna is just a 1/2WL dipole. It should work well on
40m-10m.

> Ummmm wouldn't it be easier to just trim the whip?

Yes, but this is not what Ken was asking. I gathered he wanted to leave the whip at a length that would work in the CB band, and add a siple matching network for operation in the 10M band.

>I used to easily work Japan from my pickup in Portland Oregon with 25 watts,

When 10M is open you can work anywhere with just about anything. During a recent 10M contest I worked all over the world using a 8' loaded dipole indoors and 10 watts.

> Is this solid, or nonsense?

You have the basics OK Mike. Calculated lengths are fuzzy things, the trick is getting the length right out in the yard with the specific coax you have on hand. For 1/4 wave cutting purposes coax matching setions can be designed the same way coax harmonic filter stubs are designed.

There's a bunch of info on the topic in the K1TTT website and it applies to both matching and filter line lengths.

http://www.k1ttt.net/technote/onestub.html

http://www.k1ttt.net/technote/stubs.html

But then comes the realities, measuring the results of your trimming process to find out if you really do have a good 1/4 wave line when it's done. The handiest way to do this is with an antenna analyzer. The manuals for the MFJ 259/269 analyzers illustrate (educate) how it can be done rather simply with any analyzer and can be downloaded as a .pdf from the MFJ website.

>
> - Mike KB3EIA -
>
> Now I wonder how that all ties in with changing that 100 Ohm impedance
> to 50 Ohms?

See chapter 26-6 of the ARRL handbook (19th ed., 2000) "Coupling the Line to the Antenna".

Za = Antenna feedpoint impedance = 100 ohms
Zf = Feedline impedance = 50 ohms
Zm = Required characteristic impedance of a 1/4 wave matching section = ?

Zm = Square root of (Za ï¿½ Zf)= ?
Zm = square root of (50 ï¿½ 100) = 71 ohms.

Often with coax, the velocity factor is taken into account. RG-58 is 0.66,
so it comes out shorter than a quarter wavelength.

All the questions answered? Any topic is eventually tiresome, but not everyone tires of it at the same time. Gain per unit length is likely not a straight line at any particular frequency. There is probably much more to be said about best coupling for maximum gain.

There was an article by Joe Reisert, W1JR in the December 1986 issue of "Ham Radio" about a 28-element, 21-foot boom, 432 MHz (about 70 cm WL) Yagi Joe built. The gain was about 19 dBi, or about 0.9 dB per foot at 432 MHz.

The pattern shown and gain are said to come from MININEC.

Best regards, Richard Harrison, KB5WZI

That was a 24 foot (7.3 wavelength) antenna, with 19.15 dBi claimed,
which was actually higher than newer modeling programs give it.

Oops, my mistake, 10.5 wavelengths, and about .9 dB under what it could
be, assuming the model is correct for mininec.

Dear Gary,

I have only had one person send me a message about the program and he
said nothing about any problem in downloading. Could you tell me
whether you are clicking on the link while at my Web page or are you
using the link that I put in my posting to rraa?

If you are not successful, send me a message at w9dmk@crosslink.net,
and I will send it to you as an attachment.

<< There is probably much
more to be said about best coupling for maximum gain. >>

Maximum Gain, that seems to be all people think about.

Max. Gain is not always a good thing.

Example which is better for 2 meter mobile a 1/4 wave 0 dB whip a 3 dB 5/8
wave or a 6 dB collinear ?

A true 6 dB collinear makes a very poor mobile antenna.
Unless your parked on level ground, then it works fine.

The 3 dB 5/8 wave works good if you are on fairly flat terrain.
But get into the mountains or use repeaters that are on
10,000 ft. + mountains like we have here in WY and Colorado.
A 0 dB 1/4 wave whip can some times work better.

People put a 3 dB gain mag mount on the back corner of the
finder, setting at a 30 degree angle and wonder why it don't work as well as my
0 dB 1/4 wave mounted in the center of the roof of a van. (Mounted in a hole
in the roof, not a mag mount.)

All I am saying is there is more to an antenna than Max gain.
What about bandwidth, pattern etc.

There, I feel better.

From: "J. Laub" <wd0bka@netscape.net>
Message-ID: <10o5oubahfqjd30@news.supernews.com>
Source record: 87416

I'd like to construct a 15m vert that does not require use of my MFJ Versa Tuner II. Portability. I started over this afternoon on a new vertical using plans from a web site.

WIRING:
I've suspended an 11'1" #12 wire for 15 inside some pvc. (While I was at it I also suspended a 16'5" #12 wire inside the same piping for 20m.)

RADIALS:
I've got six underground radials, 2 @ 11' and 4 @ 5-1/2"

FEEDER & CONNECT POINT:
Using 52ohm RG58 (the thin stuff) to feed into a female coax chassis mount at base of system. I have a small (maybe 4") of line from the center of the chassis mount leading to the connection point bolt/wing nut for each/either wire. This wire is 4" and I suspect this 4" may cause some electrical lengthening right? If it does, I'm over on measurements for each. errr....

Other than this possible lengthening, I cannot think of what else to do.

In short, I should probably borrow a dip meter and check for impedance problem? I was reading that I should attach a silver mica capacitor across the wires. Haven't tried this yet as they are still in the mail.

I was thinking ahead too when I put this stinker up. I've got a 22-turn base coil sitting there as my next try but that sort of defeats my original simplicity plan.

Son, you forgot "loss".
When I drilled that hole in the middle of the roof of the brand new Durango,
I married that truck.
Then there are the two BIG holes, one in each rear quarterpanel.
At 90,000 miles I'm about to do the FIRST brake job; It's an OK truck.
Anyone remember how Chrysler's still in business?
Anyway, here's my rig:

Comet 144/222/440 on an NMO mount topside center, small Hi-Q screwdriver 5' above ground on the left rear quarterpanel.
Tarheel 4' screwdriver 4' above ground with a 4' whip on the right rear quarter panel, toroidal transformer matched for 20 ohms.
For 160/80 I also have a BIG Hi-Q for the right side.
Rigs are Kenwood: 742 and 480HX.
No tuners.

A simple antenna is resonant at one fundamental frequency.
Get your hands on one of the new cheap antenna analyzers and find that
frequency.
Improve your counterpoise and adjust the radiator's length to make your wire
resonant where you want it to be resonant
("resonant" = a purely resistive load).
Then match the antenna's impedance (surely <50 ohms for any 1/4 wave
vertical) to your line with a tuner or transformer.
BTW tuners suck.
Power.

qsl.net is notoriously slow. Anybody with a fat pipe (I got T1 at work) can
see this. I tried today and got nowhere, both with the link in the post and
on the website. Too bad, these look like great programs. I would be
willing to PAY for them on a cd.

You may have to use the base coil to properly match this vertical. A 1/4
wave (with a reflected image - Marconi style) will have a 36 ohm impedance
at the feedpoint.

Lynn,
I have used a Terk FM amplified antenna (Terk Tower, the older version
I have is FM only) in the past and it worked fine. I was in a bit of
an "RF Hole" where a twinlead dipole just wouldn't cut it and the Terk
pulled in the stations I wanted. The gain setting was kept very low
for all but one station. Fortunately I don't have reception issues
where I'm at now but I kept the antenna just in case 8-} I'd
recommend their products based on my [single point] experience with
them. This may be an easier option for you than the attic antenna -
the new Terk Tower includes AM and sells for $29.95 at Best Try
..... oops, I mean Best Buy. Gotta love the Best Try description:
"Omnidirectional antenna; also has directional antenna capability"

Dear Bill,

Slow is relative. For someone like me with a V.90 modem, everything
seems slow. I get the same download speeds from QSL as from anywhere
else - about 4 kBytes/sec.

Getting the software on is easier than you might think. I will try to
honor such requests for what is essentially my costs, so long as the
volume of requests isn't too high.

Anyone who sends me a Self Addressed 6" x 9" clasp type manila
envelope with a dollar bill in it gets a CD by return mail.

Well, OK there is just as much crap here but the posts in RRS do not
usually turn into a "thesis" or degenerate into soap operatic techno
babble with the usual cast of characters.

Generally, the air of pretense does not exist in RRS, as people here do
not claim to be other than nonprofessional on the subject.

Oh yeah and you are wrong about the shielded loop.

Hi Richard
Unfortunatly shortly after making his last post Art was
rushed to hospital and underwent emergency surgery to remove a
miss-behaving gall bladder.
At the time of writing I have been informed he is recovering and
hopes to be home in about a week or so.

Regards Derek unwin

Is there a difference between a "Skywire" coax cable and a regular coax cable you get from Radio Shack in terms of quality or compatibilities?

I've never heard of "Skywire" coax however I can say that the coax
I've seen from Radio Shack doesn't have good braid coverage of the
dielectric - perhaps 75%. Times Microvave "LMR" series is good coax
and I've also found Belden and International (their 9096 which is a
Belden 9913 equivalent) to make good quality coax.

The way I view it, if you're spending good money on an antenna and
going through the effort to install it (whether on a tower or roof
mounted mast) it pays to spend a few extra dollars for a quality
feedline, and to adequately weather-proof the connections.

I think Grove Enterprises (reseller of equipment and publisher of Monitoring Times) might have trademark to an HF antenna called "Grove Skywire". It is an insulated coax-type antenna that functions as a long wire or random wire, depending on how much of it you put up.

Radio Shack's RG-58U is a heavy duty and reliable coax that provides many years of low-loss service. I eventually replaced all of mine with more expensive Belden equivalents but doubt there is much difference in velocity or shielding, etc.

Hi Bob -

Thank you very much for making these available!

I just downloaded SmartSmith from your qsl.net links,
and I'm looking forward to trying it.

BTW, qsl.net WAS spectacularly slow, averaging
0.5 kB/s. It's a good thing this was "only" 2MB.

I hope this is posted in the correct forumï¿½.

I'm looking for an indoor (or outdoor attic mount if necessary)
antenna that will allow me to get local NY TV stations in the
Philadelphia area. It's about 2 hours or 120 miles from the source; I
believe either the Empire State building or Palisades Park NJ. I'd
appreciate any suggestions as I'm NY Giants fan stuck in southern NJ
(Philly Eagles territory).

Thanks,

Brian D.

Hope all goes well and he is back to antenna stuff soon, wishing speedy recovery.

While speaking of gall bladder, my XYL had bad attack of gall stones, instead of going for operation we dissolved the stones with apple juice/lemon jucie/oil tretment and avoided the knife. Worth looking into it and do it as preventive measure from time to time. Info is on Internet pages under alternative medicine.

Brian -

IF you live 120 miles from a TV transmitting site, you are in a "deep fringe" reception area. This will require you to get as much physical height and outdoor antenna - that is available for reliable reception. Winegard, AntennaCraft and ChannelMaster have model that could meet that requirement -- on a 40 or 50 foot tower.

I would recommend that you consider a satellite TV service (DirecTV, DISH) that has the NFL choice package - you get all of the sports you desire -- solid picture -- for about same amount of $$ . You are allowed by FCC (federal law) to have an outdoor satellite dish ... if you have problems with a landlord / building owner or homeowner's association - send their legal council to this web site:
http://www.fcc.gov/mb/facts/otard.html

gb

That will address that problem.

Jack -

When buying coax -- be a "doubting Thomas" - there is a large amount of "junk coax" on the market. In fact many CATV companies are now replacing poor quality homeowner installed coax -- in order to handled new digital channels, Internet and phone services (up to 2 GHz).

When I buy Belden (or Times) I know what I am getting, its quality and consistency. I also purchase some coax versions by Press, TheWireman. http://thewireman.com/index.shtml

I have known Press a number of years, and will ask him to look at the shielding, braid and jacket formulations. The especially like his marine RG-8X which meets unique marine and water/wet installations.

As for RadioShack, I do not use them for coax purchases. They are becoming a cell phone retailer (and battery operated toys for Christmas) in many parts of the country.

Allied Radio is no longer part of RadioShack - and it shows. While some franchise owners and stores work to meet local needs, I do not find this on a nationwide basis.

I tuned mine (with able assistance of Bob, WV7W) by putting one
resonator/coil on top, tuning it, removing it, then repeating; so each coil
was tuned independently of the others. Then, I tested it with all coils (I
have all six - 3.5,7,14,21,24 & 28) attached. It's worked for over a year
so far.

Unexpected success. On the 16'5" leg of the antenna by dumb luck of
where I place the alligator jumpers found a 1.3 match on 40m! Though
this is not the freq where the antenna is supposed to be operated on it
does tell me that the coil is working. Once I get my hands on ant
analyzer I think it'll live.

Some of us have gotten spoiled rotten by our wideband connections. I for
one have a T1 at work and do most of my downloading there. Maybe it's time
to step back, take a deep breath, and recall when we had a 1200 baud modem!
;^)

Thanks again, Brian. I did the stub at their reccomended length, and it works well. 1.5:1 across the whole 20 meter band, and now the upper bands are in line also. Fascinating, I'm gonna do my homework now! 8^)

Dear BB,

Amen!

My first experience with "dial-up" was in 1965. I was asked to try out
a program in Basic that designed electric motors. You had to dial up
this big main frame in Boston - Dartmouth, I think. We had a teletype
as a terminal and an acoustic modem at 300 baud. The acoustic modem
was a telephone handset with sponge cups for earpiece and mouthpiece
that snugged around the telephone handset. Acoustic coupling means no
electric connection - good for lightning isolation - Hi!

You typed in your Basic program and tried it out. If you wanted to pay
a monthly fee for storage you could save your typed in program on
their disk for a monthly fee. Talk about a text based interface -
primitive doesn't even begin to describe it.

I am tickled to have V.90 at somewhere above 33 kBaud. It makes your
head swim to think about where it will be 5 years from now.

Cecil Moore wrote:

Seems everyone must be suffering from post tramatic syndrome on this one.

Here's the bottom line.
Does a center-loaded mobile antenna have a cosine current distribution? No.

Does just the coil have a cosine current distribution? Close to one but
it may not start at zero degrees like a thin-wire dipole does.

Does displacement current have an effect? Yes, but the effect is
close to the same for the forward current and reflected current.

Do I^2*R losses have an effect? Yes, but the effect is close to
the same for the forward current and reflected current.

Does radiation "loss" have an effect? Yes, but the effect is close
to the same for the forward current and reflected current.

Whatever effects exist that affect the current, the forward current
and reflected current are affected close to equally.

The net current anywhere on the antenna is still the phasor sum of
whatever forward current and reflected current exists at that point.

Any phase shift through the coil is multiplied by two by the two
currents traveling in opposite directions with opposite rotations.

Can one subtract the number of degrees occupied by the conductors
from 90 degrees to get the number of degrees occupied by the coil?
No, it's not that simple.

Is the current at the top of the coil higher than predicted by the
above simple calculation? Yes.

Does the coil occupy zero degrees? No.

If the coil doesn't occupy zero degrees, the net current at the bottom
of a coil and at the top of the coil cannot be the same value when the
coil is located in the middle of an electrical 1/4WL antenna.

Are there special cases where the magnitude of the current at the top
and bottom of a coil can be equal? Of course, but the typical loaded
mobile antenna is not one of those special cases!

# 1558. Coax antenna for aircraft, help.

Newsgroup: rec.radio.amateur.antenna
Date: 2004-10-31 05:10:10 UTC
From: "Carl J. Hixon" <cjhixon1@cox.net>
Message-ID: <jo_gd.85932$hj.69553@fed1read07>
Source record: 87353

I saw the following antenna being made by some ultralight guys in San Diego. I was wondering what to think of this. I am new to antennas and just starting down the path to hamdom. Anything I need to know before starting to experiment with making one? I don't want to fry my only radio, a Vertex Standard VX-700.

Below are the plans for an antenna which does not require a ground plane.

This antenna is a 1/2 wave vertical dipole made out of RG-58/U coax and a Radio shack FM radio antenna. The beauty of this design is that it is cheap, simple, and easy to make with readily available materials. The radiator should be 3', 9 1/2 inches long for 123.450 operation, but only the top foot or two needs to be the telescoping FM radio antenna. Or, you can make the entire radiator length out of regular antenna wire if you wish. The only critical thing is the total length.

Start out with enough coax so that you will have enough to run up to the radio from your antenna mounting location.

First, solder the telescoping antenna to the middle conductor on the coax. Make sure to strip back the shield far enough so that it does not short to the "radiator" or telescoping part of the antenna. Remember, you can make the "radiator" entirely out of the center conductor on the coax, so if you are going to do that, you must make sure the dimensions are correct. Next, on the other end of the coax, I cut off a piece of coax that is going to be the shorting stub. In all cases, I always make the lengths to the long side. This way the antenna can be trimmed in to the desired frequency with a SWR bridge.

To connect the shorting stub to the feedline, carefully remove a small section of insulation from the center conductor (no more than 1/4 of an inch). Solder and tape the inner conductor, then join and solder the shields. To insure proper shielding, split a spare piece of braid lengthwise on top of the shield connection, and carefully solder the shield together. (Rather than disecting the coax cable and soldering, we used a BNC connector for the shorting stub. We then trimed back for tuning and ended up with almost no wire needed on the shorting stub. VERY SHORT.)

Don't forget to put a BNC connector on the radio end.

Finally, hang up your antenna in an open space, and tune it in with a SWR meter. I have found that adjusting the length of the shorting stub has the most affect in adjusting for minimum SWR but be careful. If you cut too much off you will have to re-do it.

Radiator Length: 3' 9.5"
Radiator to shorting stub: 12.9"

Shorting Stub: 1.9" (imagine no BNC connector when
measuring)

QUESTIONS:

(1) So how do I calculate lengths for other frequencies? ie 121.5MHz,
146.73MHZ, 123.0 MHz
(2) Any chance of damaging my Vertex Standard VX-700 if I start playing
around with this?
(3) Where can I finde a descent but cheap SWR meter?

Thanks,
Carl

Hi Carl,

By the numbers:
>(1) So how do I calculate lengths for other frequencies? ie 121.5MHz,
>146.73MHZ, 123.0 MHz
By the proportion to the original frequency (this is called scalable).
This usually implies thickness too, but the variation of your
frequencies is slight enough to disregard. Besides, you need to
anticipate some trimming using the SWR meter you are asking for in
(3).

>(2) Any chance of damaging my Vertex Standard VX-700 if I start playing
>around with this?
Not particularly for low power and modest SWR (and probably not even
immodest SWR).

>(3) Where can I finde a descent but cheap SWR meter?
Radio Shack.

> at it I also suspended a 16'5" #12 wire inside the same piping for 20m.)

That may be half of your problem. #1, the PVC may be effecting the
overall length of the wire a bit. #2, if you have another vertical
wire right next to it, they will couple and all bets are off. You are
not tuning on 15 because with that extra 20m wire next to it, you are
now too long I bet.
>
> RADIALS:
> I've got six underground radials, 2 @ 11' and 4 @ 5-1/2"

Another comment...Ground mounting a 15 or 20 meter vertical is never
going to be that great a performer. You would be much better off with
something elevated off the ground. Of course, I realize this may not
be possible in your case.
>
> FEEDER & CONNECT POINT:

You should not need *anything* to match a 1/4 wave vertical. I know I
never have, on any band, or with any ground condition. If it doesn't

tune at least under 2:1 SWR, something is wrong... Like running two
verticals an inch apart...
You also shouldn't need any fancy analysers...I've never owned one
myself, and I don't have any trouble.
>
> I was thinking ahead too when I put this stinker up. I've got a 22-turn
> base coil sitting there as my next try but that sort of defeats my
> original simplicity plan.

You shouldn't need it. Just curious...If this is going to be a
portable antenna, what are you going to do about radials? Are you
going to add ground radials at each location? What a pain....
For a portable 15 m vertical, I would use something like a base fed
half wave.
Can be mounted anywhere, no radials are needed. Can be elevated, or
near the ground, although the higher the better. But, you can get what
you have to work, if you ditch the 20m wire that is next to the 15 in
the PVC. Or at the least, ditch it until you get the other band tuned.
In the real world, if you tried to make such a dual band antenna, it
would be best to tune 20 first, and then 15. But I don't really
recommend you doing that as it's a PIA to tune. I'm almost sure thats
most of the trouble you are having. The PVC could be effecting the
overall length also. MK

Colin Powell's little boy will be giving us BPL any day now and our
problems will be over. [g]

Interesting that CFR Title 47 part 97 states in part:

"Sec. 97.1 Basis and purpose.
The rules and regulations in this part are designed to provide an
amateur radio service having a fundamental purpose as expressed in the
following principles:
(a) Recognition and enhancement of the value of the amateur
service to the public as a voluntary noncommercial communication
service, _particularly with respect to providing emergency
communications_." (emphasis added)

And yet the ARRL reports on the latest BPL news:

"We similarly do not find that Amateur Radio frequencies warrant the
special protection afforded frequencies reserved for international
aeronautical and maritime safety operations," the Commission said.
"While we recognize that amateurs may on occasion assist in providing
emergency communications," the FCC added. It described typical amateur
operations as "routine communications and hobby activities."

I guess during the next forest fire, earthquake, tornado, hurricane,
boating accident or terrorist attack we can just sit back and play
with our toys while all of the real communications takes place on the
Internets, as GWB would say.

For outdoor, flexible coax I have found that Bury-Flex (TM) from Davis is ideal. This link takes you to the part of his site where quality coax may be found:
http://www.davisrf.com/ham1/coax.htm

It is daft not to use good coax. As others have observed, No-Brand and RS should be avoided.

I see a few TV antennas in my neighborhood that are pointed exactly
180deg the wrong direction with the longest elements toward the station
and the ï¿½top wing boomï¿½ end pointed away from the station. This usually
happens in clusters, where one neighbor looks next door to see where the
antenna is pointed (wrong), and so onï¿½.
If this were the case it would explain diminishing UHF signal strength
due to the higher front to back ratio when the corner reflector elements
are installed.

Around 1970, our regular terminals were TTY, and High speed was an IBM 2741 (I think); blazing fast at 300 bps, faster than you could type. A few years later we had 9600 dial up service to the West Coast, but had to use two modems and dial two telephone numbers.

> Hi Carl-

Tho, the rest are ok- must disagree on the SWR bridge, as some of those cheap
ones (Swan Electronics was a good example, among others) used lousey sampleing
circuits in their directional couplers. What does this do?? well, as these
are NOT even close to 50 ohm , and a substancial part of a 1/4 wave, actually
introduce a mismatch! It is easy to test for- simply terminate the antenna
with a 47 ohm 2 watt resistor, and measure the swr -should be 1:1-- then reverse
the meter and measure the swr -backwards (set the pot , in the REFLECTED position
then measure the swr in the Calibrate (or forward) position again should read 1:1
I have seen some (like the swan) reading greater than 3:1 at even 6 meters! Also,
on very high swrs, have actually seen "more" power return than was in the calibrate
position (a impossible situation !) This is caused you the lousey directional couplers
in the meter, itself!
These were made for CB, not for VHF! If it doesn't pass this test- would be a good idea
to try another brand or (perferaably) borrow a Bird (or equivalent). As information--

Hi Bob, thanks for the new Smith program. I did have a problem downloading it, and still don't know if it's all there.

We're returning to Florida early tomorrow morning, and once I get the external drive connected down there I'll determine if your program is in working order. If not, I'll email you for a new download.

So far, it looks like a real winner!

Walt

Tom,

Kerry went to congress to parrot the issues
of other Viet Nam vets. The repugnant party
- the party of lies and deception - spins this
event to malign a true war hero.

http://freerepublic.com/focus/f-news/1097982/posts

In contrast... any leader who's army invades
a sovereign country that is not an immediate
threat to the invading country, is, according to
international law, a war criminal.

Yes, Saddam was a first-class jerk and two-
bit tyrant, but was not an immediate threat to
America - he lost 2 wars and was sanctioned
by the UN - his army was left impotent, his
major weapons were destroyed after the gulf
war, his WMD programs were in shambles,
and there were no proven ties to al Queda.

GWB is a war criminal - too bad you support
a real war criminal - and that's not spin.

Hi Reg, Since this is an Amateur Radio Newsgroup, why do you think we should all be real engineers? Do you write all of your excellent programs for the sole benefit of the real engineers?
I have used your programs, Smith Chart Programs, and a number of others that I have found to sucessfully design antennas and matching networks. If I had to choose between your programs and the Smith Chart, I would have to say I like both.

Neither ATTACKED us, nor THREATENED US! To state otherwise
means GREMANY ATTACKED PEARL HARBOR. And, JUST WHAT GIVES THE UN
a free pass?? That institution , run by 3rd world DESPOTS, has any
creditability in the scheme of things, is like saying that Heidrich
loved the Jews, and was legitimate in the "benevolent treatment" of them,
during the war! The facts are that : KERRY is a admitted WAR CRIMINAL,
and comitted ATTROCITIES-- to state otherwise is to say that those
POW's that were tortured - deserved THAT TREATMENT- on Kerrys own testimony.
And, as WE WERE ATTACKED ON 9/11, we were as justified in retaliating
as in ANY period of time in the history of the Republic-- or are you
willing to SERVE A SUMMONS to these idiots, and say that they are being sued ??
To even try to justify your position is to beg for further attacks. But, I

guess you think that the World Trade Center was Justifiably attacked, or worse-
WE DESERVED IT ! Jim NN7K

Germany declared war on the United States 11 December 1941. When did
we attack them previous to that date?

Well, the answer to that is that the Destroyers Greer, Kearney and
Reuben James attacked German submarines. THIS is the Nazi explanation
for their declaration.

In fact, the USS Kearney, DD-432, was torpedoed by the U-568 on 17
October 1941. Six weeks before, the U-652 attacked the Greer.

Well, I suppose Roosevelt melted under pressure to leave Adolf alone,
but then we had the sinking of the Reuben James 30 October 1941 (63
years and a day ago).

For these affronts to their national dignity, the Nazis had no choice
but defend themselves against us - and, well, one thing led to another
as the saying goes.

Carl -

Try HRO - Diamond makes some nice meters for under $100.00 - for instance:

Item : SX-40C
Description : 15/150W 144-470 MHZ COMPACT WMTR
YOUR HRO PRICE $79.95

My vote goes to such luminaries as Genghis Kahn, Attila the Hun, and
Timur the Lame, all of whom did what George just did. Seriously,
fellows, you can get it out of your system just by voting on Tuesday.

Hi Tom,

DOING better than that. I got myself involved, been working 70 hour
weeks for a month, helped register 2800 voters, and collected about
100 ballots BEFORE November 2nd. And then there is Poll Watching to
be done ON the 2nd.

Come what may - either way - it isn't what is going to happen on the
2nd that counts, it is going to be what happens every day AFTER
Tuesday for very many years.

Where was the technobabble? It made sense to me...
>
> Generally, the air of pretense does not exist in RRS, as people here do
> not claim to be other than nonprofessional on the subject.

Well, some on rraa *are* professionals. But again, many are not. I am
not. My work has nothing at all to do with radio, antennas...
>
> Oh yeah and you are wrong about the shielded loop.

Oh yeah? Prove it. I've built both, and tested both, and I couldn't
tell a lick of difference. I have also used both shielded loops and
plain wire loops for the "coupling" loop that feeds a regular wire
loop. Again, no difference in noise pickup.
None whatsoever. If I am wrong, why don't I see the results? I'm not
just barking at the moon. I've built and compared both types just to
test this exact theory. Both of my present loops are now plain wire.
Don't you think that if there were really an advantage to a shielded
loop, I would be using them? My mama didn't raise a total fool. If I
see something that works according to common lore, I'll say so. If it
doesn't , I'll say that too...So far, I haven't seen it...
It's still my opinion that the shielded loops *do* help ensure balance
in feeding, but as far as a magical "anti noise" property, I don't see
it. If you feed the plain wire loop in a manner that also ensures the
same balance, both antennas will respond to any noise in the same
manner. You can disagree, which is fine, but until I see proof of this
magical anti noise property in real life, I will continue to claim the
*lower noise with a shielded loop theory* is a bunch of malarky... MK

Hi Carl,

A quick check at their web site reveals:
http://www.radioshack.com/iphraseget.asp?perPage=25&groupBy=&sortBy=iphrase+relevance&command=eq&attr1=Category&attr2=%3ARadio+Communications%3AAmateur+Radio&q=25&ia=1&s=%24__session__%24&s0=iphrase+relevance%2F%2F0&t=0&i=oid&c1=i%3A770%3Bdescription%2Cproduct%2CCategory%3Bswr%2Cmeter%3B%3Aswr%2C%3Ameter%3B%2B0+%2B1&c0=e%3A140%2F%2Fotype%2F%2F%3Aeq%2F%2Fsku&s1=oid%2F%2F1&as=1&render=1&domains=rscatalog%3Aoid&text=&sf=
or simply put SWR Meter into their search engine.

Lee's suggestion is just as good too.

As for simple instructions, the web abounds with them for 2M, you
simply scale any one of them to your frequency. You could build one
for less than $5 and it would mostly be for the SO-239 connector that
is used as the basis for a quarter wave vertical with four radials.

Use ordinary #14 solid wire:
Vertical wire, 21"
each of 4 radials, 13"
droop the radials at 45ï¿½

...or so my quick measurements show. Your mileage may vary. Consult
other authorities for a sanity check.

>>
>> Was created by the United States, in San Francisco.
>
>Yeh, and also the League of Nations

In fact the League of Nations was not created by the United States,
and certainly not in San Francisco.

>Is George Washington, Jefferson,
>Adams, Franklin, ect. to be considered criminals

They were - consult any British source of that era.

>Is Ho-Chi Minh Castro? Stalin?

So were they - consult any American source of that era. As you offer,
it is merely the source of the who builds the indictment.

Curious point about this last bunch is that they all read and used the
writings of Washington, Jefferson, Adams, Franklin to achieve their
goals.

Ho Chi Minh modeled himself after Gandhi. Gandhi modeled himself
after Thoreau ("Civil Disobedience"). Do you count Thoreau among the
criminal element? Thoreau willingly embraced such a label. Was
Gandhi a terrorist? Ask the Brits - then ask the Indians - then ask
the Pakistanis - then ask the administration. :-)

3 out of 4 will give you a straight answer and the last will offer
"It's hard work!."

Absolutely none of the radical communists learned their craft from
those bourgeois elitists Marx/Engels, they only peddled their DOA
ideology. ALL of their success came from AMERICAN examples. ALL of
their failure came from communism - plain and simple.

Carl,
I know that this isn't the answer you are seeking but I'll give it a
go anyway. Whay not just use a quarter wave? If your ultralight
aircraft has a metal framework and/or skin you could use that as the
'missing half' and just use a 1/4 wave whip. This is done in land
mobile all the time, a 1/4 wave whip that uses the vehicle body as the
ground plane. While I might be missing something by not knowing much
of anything about the aircraft you wish to mount this on it seems like
the simplest solution. I've built 3 from published measurements and
the SWR was acceptable on all (under 1.5:1) without pruning. Figure
the center frequency of where you plan to operate (on each band) cut
for that and call it a day. If you do wish to get the SWR meter
anyway another poster recommeded a Daiwa - I have one of their SWR
meters and concurr with his recommendation.

Your judgement only. Odd, the only time Kerry managed anything, he left with
270-some "employees" pissed at him; and they still are, 35 years later.

> or WMDs that didn't exist,

Sadaam didn't need WMD to invade Kuwait or to threaten Saudi Arabia. He certainly had some previously, and had no compunction about using them. To me, WMD are a non-issue; it's not what he didn't have, it's what he did that matters.

> or the

> 146.73MHZ, 123.0 MHz

For a half wave it's 5616 ï¿½ frequency in Mhz = Radiator length in
inches.

For a quarter wave it's 2808 ï¿½ freq.

> (2) Any chance of damaging my Vertex Standard VX-700 if I start playing
> around with this?

No. It protects itself, don't worry about it.

> (3) Where can I finde a descent but cheap SWR meter?

There is great beauty in the KISS theory. Don't bother with an swr
bridge for no-brainers like this with an HT, it's overkill for any
purposes, close enough is close enough. Cobble together two antennas,
one for the air band and one for the 2M ham band, swap antennas
depending on the band in use and be done with it which is easy with
BNC connectors.

The simplest cheapest type of VHF antenna is the ï¿½ wave coaxial "no
radials vertical" and is made from RG-58. Calculate the length of the
ï¿½ wave radiator minus one inch to roughly correct for the velocity
factor and strip off the plastic jacket to that length plus ï¿½ inch.
Don't strip the insulation off the center conductor. Then horse the
braided shield back down over the jacket of the coax toward the radio
end. Lay a length of nylon cord alongside the radiator which extends
some number of feet beyond the upper end of the radiator. Seal the
whole assembly with heat shrink tubing, plug the top end of it with
some Goop and hang it up somewhere handy. This is not a particularly
portable "shack on the belt" sort of solution but it's essentially
bulletproof.

I strung one of these up in the airframe of my Quicksilver MX in my
ultralight flying days and it didn't just work, it drove me batty, at
altitude I heard every weekender UNICOM chatterbox for a couple
hundred miles around and I quickly retreated back to the rubber duck
to get some "attenuation".

This is why I move the wires to the outside of the pvc. I have at least 2" of separation between wires now. In addition to the ability to tune up on 40m w/o transmatch have noticed that generally speaking it tunes much easier on each band when use the ant tuner. I bet the wires, when strung on the inside, were crossing over or too close to each other. In any event, my next step is to obtain an analyzer and move the alligator clips around on the load coil. Once this beast is functioning, I am going to write up a short how-to for the web site. This pvc actually looks okay in the backyard.

> compatibilities?

One thing I didn't see mentioned in the other posts is the quality of the wire used to make the coax.

I have seen this problem with both Radio Shack Coax and their hook up wire. I beleive it is all made in Japan and they use a different copper alloy (or possibly tempering) than the US companies. This makes the wire more brittle and it tends to be stiffer. Read this as: You have to be >>>Very<<< careful not to nick the wire or it will break when it flexes. The US made copper wire I have used does not have this problem.

>
>
> Thanks,
> Carl

I don't know if I am understanding the instructions correctly. I take them to mean that the 3' 9.5" antenna is attached to the end of the coax and then you come back away from the base of the antenna 12.9" and splice in a 1.9" piece of shorted coax. If this is true, then working backwards from the stub I find that the antenna is about 2.4-j73 Ohms. Seems a bit strange for an end-fed half wave, but never mind that.

In any case, to adjust the lengths for a new frequency, simply divide 123.45 by the new frequency (in MHz) and then multiply the dimensions by this number. This is what Richard meant by scaling the antenna for different frequencies. For example, for 2 meters, you have
123.45/146.73 = 0.8413 so your antenna will be .8413 times 3' 9.5" or 3' 2.3". Adjust the distance from the antenna to the stub and the length of the stub in the same way.

I recommend that you build your own SWR meter. The one I have in mind will actually provide protection for your rig while you use it. It is a resistor bridge type. Read about it here:

http://www.qsl.net/xq2fod/Electron/swr/swr.html

He uses two meters, which I would not do (use a switch instead).This circuit can also be found in the ARRL literature and where it uses just one meter.

Frankly, I agree with other posters here in that this antenna could be very troublesome for you. Adjusting the shorted stub and its position on the feed line could have you pulling your hair out. Small errors in dimensions will have large impacts in SWR. Be sure to look at your SWR when the antenna is mounted in its new home. Proximity to other objects may have a big effect.

Good luck.

John

>

Hi Ian,

According to my OED, Ballot has existed in the sense we all use it since 1549. I can't imagine which "Mericans" you could blame then. The notion of not being cast is foreign given the word Ballot derives from Ball, and if anything, for it to work as a secret vote (the meaning of Ballot according to the OED) it had to be placed into a Ballot Box (and having had stood next to one for these several weeks makes me a Balloteer) about as remote to being held as any.

Others may appreciate that this all devolves to the idiom "Black Ball." That is, the Ballot indicated if you voted For or Against and you held it hidden in your hand and deposited it unseen by others into the pool of other Ballots which were then reckoned after the completion of the process. If the majority were black, the candidate was defeated.

Anyway, back to my Ballotist activities. I've got more Ballots to collect.

Actually, Mark is right. For small loops it shouldn't make any
difference according to the theory in the Antenna Engineering
Handbook. Shielding larger loops may help deepen the null, which
is good for direction finding, but it isn't supposed to do anything
for small loops.

Oops! I forgot to include the velocity factor of RG58A. Using .73 would make
the antenna 23.9-j199 Ohms. But, this estimate is not really useful to you
and I probably should have left out that whole paragraph. Just ignore it.

Hi Richard,
the present administration sure has revivified the
democratic process by angering everyone it could, and re-starting
the culture wars. I don't think a different president will change
foreign policy much, though. Once a nation gets as mighty as
ours, it seems to get power-drunk therefrom and blows all its resources
on controlling the world. The next four years should be interesting, but
painful, no matter who controls the White House.

An abstract math equation will get one the answer but not necessarily
illustrate what is happening in reality. We see the results of that here
on this newsgroup. The appeal of the Smith Chart is that it gives one
a graphic conceptual grasp of reality while using those same equations
to solve the problem. A picture *is* worth a thousand words. We can
see the (Vfor+Vref)/(Ifor/Iref) impedance displayed right there on
the SWR circle.

Perhaps I give greater credibility to the folks
who served with Kerry in this regard, than
the vile rhetoric of folks with an un-American
religious/political agenda. Kerry was not alone
in his distain for that war, but the hawks who
opposed his position then, are still carrying a
grudge now - after all these years - that's both
obsessive and perverted IMO!

When a President has more loyalty to his
mega-corporate cronies and the looney
megalomaniac Pat Robertson, than he has
for the common folk, he does not deserve
to hold the office.

Hi Bob,

What a dissapointment - spending so much
time in downloading your progam (three
attempts), only to have it fail in its installation.

Your installer told me I have an outdated file it
needs to replace. Afer allowing - and rebooting
- the installer did not continue. When attempting
another install, I get the same response... ad
infinitum.

I can't deny its small educational value. There are other things besides transmissions lines. Its worth a single lecture in a 3 year course as are numerous other graphical methods of illustrating electrical principles..

But unless one is made aware of its limitations and its inaccuracies (which takes up half the lecture) it can in fact damage an education and turn a student into an old-wife.

But it's fine for old-timers who've had years of practice and can use it with their eyes shut as they already know the answer before they start.

It is a paper instrument which assists in performing very simple algebraic calculations - provided you already know what its all about.

I appreciate its historical, nostalgic, sentimental value. If you gaze at it long enough it acquires a certain beauty. And it served a very uselul, time-saving purpose when in vogue during the 1940's.

Hi all,

Looking for the really skinny stainless whip material for a mag mount two meter ant.

The current material on my mag mount is too stiff and when it hits the top of the garage door it pulls the magnet off.

Looking for the really flimsey material that will easily bend backward in the garage and not pull the magnet off.

Where can I get this material? I know with skinny material I give up bandwidth, but I only use one freq anyway.

Thanks
Tom

Source record: 87311

Hello HAMmers :)

I want to build an internal WLAN antenna for my notebook computer to be placed in the screen.
The available space is 163 x 12 mm. A quarter wavelength at 2442.5 MHz is 30.7 mm. I haven't been able to find much info about microstrip design so I hope you might be able to give some suggestions as to a good design.

I have thought about 'stretching' a bi-quad to fit the dimensions, but then the angles cannot be 90°. Would that be a problem? Can you suggest a better design to try? This is my first antenna design so please bear with me if these are beginner questions.

Thanks

The ARRL antenna book describes the inductive effect
of traps on lower freqs and how this physically shortens
the antenna. They talk about L/C ratio and give two
examples.

Problem is they don't give the formula! #$%#%$!

Here's my antenna - it's a 75/160 trap dipole. The traps
were designed with W8VVM's software. Cutting the
75m portion of the antenna is easy - I need to know how
long (as a starting point) to cut the 160 m end pieces!

Help!

Details: the traps are 8-1/3 turns of rg58 coax wound
around a 3-1/2" form. L is 7.211 uH, C is 232.15 pF.
X is 176.24 ohms. Design freq on 75 is 3.890. Target
freq for 160 is 1.925. I plan on cutting the 75m wires
60.5 feet to start and work up from there but what do
I cut the 160m ends to start?

Try an RC hobby shop. RC antennas are what you want.
Make sure it is 20+ inches long so you can trim it
to resonance. I am amazed at the advances in RC model
planes. Almost everyone is using electric motors now.
A control servo that used to measure two inches by one
inch by 0.5 inches is now virtually microscopic. :-)

You know, I thought the same way for a while. In my land survey business, I progressed quickly into using Autocad and total stations with data collectors, but I never forgot the old ways. I could tape a 10,000 ft. line through moderate terrain with 1/50,000 accuracy/precision, and close a traverse with book of log tables and trig tables. Thanks to frequent power outages around here, and dead batteries, I got to use both. keep the old technologies alive!

Hi,

I have been recording vinyl LPs to my computer the past few days with a grounded phono preamp. I had no problems until today. I am now picking up serious hum and buzz, and I can hear broadcasts from an AM radio station that has a powerful transmitter located in my city, while using the recording software. WTF?
Is there any way to stop this bs? I have tried various isolation transformers, grounding schemes, and shielded cable configurations to no avail. I have complained to the station, but got no response from engineering.
Any ideas on what to do? Practical advice appreciated.

TIA,
James

Hi Tom,

I agree, and that is why I said it was going to take YEARS and not one
day. We live in a decadent society that has lost all proportion of
integrity, commitment, and service. When one party rails against a
dope smoking president to offer us a crack smoking president; then you
know their (plural) system has all the morality of Sodom.

Well, I've finished my rounds for this cycle of registration/voting.
It's time to move on to my next project in starting another non-profit
(my buddies chuckle that I can now lose MORE money legally).

Hi Richard,
good luck with your non-profit. Around here, selfishness,
unbridled acquisitiveness, social paranoia, and soul-deforming greed,
are all considered to be the real manifestations of morality. I hope
the American people will stop shooting each other in the back and
learn to get along some day.

Hi James,

The proper usage is
"WTF, Over?"

>Is there any way to stop this bs? I have tried various isolation
>transformers, grounding schemes, and shielded cable configurations to no
>avail.

What you describe is a ground loop. I bet you have had a weather
change in the last day or two. (I know, that is almost certain, but a
recent rainfall, or cessation of raining often introduces these
problems.)

>I have complained to the station, but got no response from
>engineering.

It's not their problem.

>Any ideas on what to do? Practical advice appreciated.

Plug ALL of your electronics into the same power strip and plug that
into the wall. Strip out all wires that go to other equipment (like a
modem, printer, T1/network connection, scanner, you name it...) make
sure the monitor shares that same power strip. You say "grounded"
phono preamp. This is probably antediluvian equipment (a two wire AC
plug with a dangling wire or knurled nut in back for ground). There
is every chance that your ground wire is going to an open ground lead
(did you check the outlet for inverted hot/neutral, hot/ground,
neutral/ground, open ground?). Is this two wire AC plug polarized?
You may have a potential suicide adapter - be careful. You might be
more successful in simply connecting the Phono output directly into
the sound card Microphone input. If it makes a hellacious hum during
the connect process, then YES you do have ground problems - you also
stand the chance of that problem going away when the plug finally
seats though (my guess is that this has always been the case, and it

just got more noticeable).

I see you have tried isolation transformerS (why the plural?). If you neglect wires that trail off to foreign connections (already listed above) this will do nothing but confuse the situation (it only takes one wire).

There is a working solution and to find it means starting with a minimal working system. Add your system axillaries one at a time until it breaks and examine THAT item and notice how it is powered, and how it finds ground. If it isn't obvious, it may be working, but it may also be broken in the sense of a safety violation (a chassis screw punctured a PC board and hit a power land - or a connector shell nut fell off and the ground is floating).

The added clue of the AM station suggests that there is a POOR connection somewhere. The sense of poor is that it is corroded (this creates a crude radio detector circuit and the amplifiers do the rest). The solution here is to break ALL connections and clean them and reassemble. Often simply twisting connectors that twist will clear the problem, or unjacking and rejacking connector jacks does the same thing. Tightening screws that hold ground leads is the same thing. Corrosion will be obvious, if in doubt, abrade surfaces until you observe bright metal. Tarnish offers the same problem. Use a typing erasure or toothpaste to clean the metal (mild abrasives).

There's no such thing as "powdered ferrite". Ferrites are ceramics, made by firing special clays at high temperatures with proprietary processes. The process is similar in many ways to firing pottery, and making a ferrite rod from "powdered ferrite" would be as hopeless as making a ceramic vase from ground-up coffe mugs.

# 1636. Re: Help designing trap dipole - ARRL Antenna book no help!

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-02 12:14:34 UTC
From: Reg Edwards <g4fgq.regp@ZZZbtinternet.com>
Message-ID: <cm7tn9$4a3$1@titan.btinternet.com>
Source record: 87230

Ken,

There are numerous different overall antenna lenghts which work as well as each other. There are also a variety of different L/C non-critical values. The only difference between them is the feedpoint impedance on the lower frequency band.

But there is only one L/C value which works with each overall antenna length. And vice-versa. And it must be the right one.

The distance of the traps from the feedpoint is determined simply by the frequency of the higher band.

If the overall antenna length is arbitrarily predetermined then you have to calculate the L/C ratio and coil and capacitor values which depend on antenna length in a very complicated manner. Unless you are very lucky you will never find the proper values by experiment.

If you arbitrarily predetermine the L/C value and hence the L and C values by guessing or copying somebody else's antenna, then the correct overall antenna length is easily found by pruning it in the usual manner. The only disadvantage is that the antenna length may not fit nicely into your back yard.

The set of simultaneous equations needed to select the L/C ratio and at the same time fitting the antenna into your back yard, can be solved without you being aware of it by the small, self-contained program TRAPDIP obtainable from website below. Download TRAPDIP in a few seconds. Not zipped-up. User friendly. Run immediately.

ARRL pre-orders were promptly shipped in October. I will have to look, but
I though this was a rework of an earlier kit.

Hi Richard,

thanks for your suggestion,

that means a T-shape as I understand?
The horizontal part should be 2 x 30,7 mm, right?
How long should the vertical line be?
How wide should I make the tracks?
The cable is a 50 ohm coax.

I did not shut down anything, but on Windows XP I got 3 or 4 messages that
said the file I was trying to install was older than what was already there.
I kept the existing files. Installed and runs OK. BTW, downloaded at about 3
KBs.

Hi Klaus,

Although perfection requires precision and accuracy, your application
does not demand perfection. Besides, it is unlikely you are either
technically prepared to measure the properties of the antenna, nor buy
equipment that could do it simpler.

There are any number of factors that would impact the measurements you
describe above and one is simply building the antenna on a piece of PC
board (why not simply use wire?). Another point is that the dipole is
a "balanced" design, and your source of radiation is undoubtedly
"unbalanced." This, of course, probably means nothing to you, and
fortunately it has meant nothing to many who have ignored this
distinction too (which underlines that perfection is not required in
ordinary, day-to-day usage). Also, you don't include enough
information to offer an exact solution.

However, to answer your question by the parts:

Yes it is T shaped (see ASCII graphic below with fixed font);

Yes, the horizontal part should be about 2 x 30,7 mm;

The vertical lineS should be as long as they take to reach
the source
and
the ground;

The Horizontal tracks could be as wide as 1mm - if you make them wider
this reduces your need for precision if you wanted to be perfect;

If you are going to use 50 Ohm cable, you don't need vertical leads.

The pictorial equivalent (view with fixed font setting):

```
----------- -----------
| |
| |
```

| |
| |
| |

Returning to issues of perfection. If you encounter problems of reception/transmission, they will be more due to the antenna orientation and placement than they will be due to power level.

Back when we lived in caves, TV came through the air instead of through a cable. We had rituals to adjust Rabbit Ear antennas (a pagan WiMax shrine) until the picture got better. You are about to embark in that same arcane practice - welcome to a brave new world.

It is a lot simpler than that...

A half wave dipole would be two tracks approx 30.7mm long as you say.
But.. you do not need a vertical line.
Coax can attach directly to the centre point.
Width of the tracks also depends on how much space you have.
The wider the tracks the bigger the bandwidth affected.

Also what may effect the whole installation is the polarisation of the
antenna,
horizontal or vertical.

This depends on the antenna on the other device. Same polarisation
recommended!

When one country (Iraq) invades and annexes another country (Kuwait), the proper response is not simply restoring the status quo. There have to be negative consequences for such aggression. Sadaam (and Iraq) never seemed to understand that concept. The fact that we did not dismember Iraq in 1991 came back to haunt us.

"Crimes yet un-committed"? How stupid do you have to be to not act in your own defense in light of clear threats?

BTW Cecil, as a "British citizen of the World", YOU don't have a Constitution. Some generation, you might want to correct that oversight.

Some things can be forgiven, some can be forgotten. But how can you savage the opinion of 270-some veterans with a judgement of "obsessive and perverted"? Of course, their feelings are being used for political influence (remember Kerry saying he was "reporting and ready for duty"). But you are way out of line to judge their memories.

I suppose your close really says it all; you say the candidate is loyal to "mega-corporate cronies" and "loonies". Ahhhh, I'm dealing with the Almighty Chuck, the mortal who can discern cronies from friends and who can define the Common Folk. Yep, that answers everything.

In addition to what Richard mentioned, you might also plug a pair of
headphones into the preamp output, and see how that sounds. Furthermore, a
turntable usually has a ground lead. Connect that to the preamp ground.
Something is acting like an antenna, one of these split ferrite cores on the
cable between the turntable and and preamp might help. Keep all leadsshort.

After the sintering step, the resultant granules are ground down to a reasonably uniform size. These powders (and I wouldn't know what else to call them) can then be compressed into pellets, extruded into rods, mixed with a vehicle and cast as thin films, or sprayed onto substrates. You can even blend them into a binding carrier (like wax or epoxy) and create physical shapes (like rods or blocks).

The density of the ferrite particles can be controlled, yielding inter-particle gaps as desired.

Ferrite exists in it's granular (powdered) form. However, since there's likely little market for this stage, you might have trouble buying a few pounds of it.

Even though I did not have the advantage of attending Texas A&M, I agree with Cecil. In classes for real electrical engineers, the Smith Chart still provides a superb means for instilling important concepts. A means that can then be reinforced with computations.
In my experience, the greatest advantage of including the Smith Chart in real education resides in the long term effects. Forever, an engineer will be able to visualize effects and be able, even on the telephone, to describe effects to another similarly "equipped" engineer. The Smith Chart is an important part of the way we communicate. Its utility insures its preservation for a long time to come.

Randy,

I value and believe in my emotions.

Now what should I do?

Seriously, "informed decision making" is a personal action that of necessity includes the context of an individual's emotions. What is informed for you may be just plain stupid for me, and vice versa. How could one ever completely separate "informed" decisions from emotions?

I stand corrected. I hadn't encountered ground down ferrite as you describe. I should have realized it existed, though, since I've used ferrite loaded paints and silicone rubber, which must contain ferrite in this form. Thanks for the correction, and to the original poster I apologize -- please disregard my posting.

Am I correct in assuming you'd end up with ferrites of lower permeability (and higher saturation flux density) than the unpowdered original, due the inevitable air gaps between particles?

A major manufacturer of ferrite-loaded materials such as paints and silicone rubbers is Emerson & Cuming. They might be a possible source of ferrite in powdered form.

Ed,

Out of line? ROTFLMAO!

One cannot give credence to a piddly few
malcontents (270 out of millions) who have
an agenda - mainly that of the Christian
Coaliton. In contrast, the folks who served
with Kerry, have an entirely different story to
tell - a credible one!

>
> I suppose your close really says it all; you say the candidate is loyal to

Almighty
> Chuck, the mortal who can discern cronies from friends and who can define
> the Common Folk. Yep, that answers everything.

It is common knowledge that the
Republican party is traditionally aligned
to the rich and powerful, which includes
mega-corporate interests - "no bid"
Halliburton included - only a fool would
refute this.

As far as loonies, I've named only one:
the one who's agenda is to "replace the
constitution with the 10 commandments"
and to "Disenfranchize all liberals".

Rather than offer a credible retort, you
attempt to demean my position.

Intellectual honesty isn't one of your
strong points, I see.

# 1653. Balun description: who is right

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-02 20:23:28 UTC
From: Johann Höchtl <johann.hoechtl@myrealbox.com>
Message-ID: <4187ec4f$0$16896$91cee783@newsreader02.highway.telekom.at>
Source record: 87248

I built an "ugly" air wound balun on a PVC water pipe according to this description
http://www.hamuniverse.com/balun.html

I get 24 turns on a pipe having 75mm (about 3 inches) diameter measured outside.

But recently i had the chance to look up the section in the ARRL antenna book and there the number of windings is considerably smaller at a higher winding radius.

Which description is right? Or does either have advantages and drawbacks?

# 1654. Dynamic dipole

I constructed a dipole. Adjusting the swr requires me to shorten the ends. As it is meant for "semi-mobile" use it will eventually become to short.

I do not want to replace the wire after a short time. Is it possible to bend the ends back a bit. If so, can i fix this bent ends using electric tape or cable tie?

Greetings,
Johann

Seems the statue of limitations on that Kuwaiti invasion would have run
out after 13 years. Should England be punished some more for invading
the United States in 1812?

> "Crimes yet un-committed"? How stupid do you have to be to not act in
> your own defense in light of clear threats?

Nowhere in The Constitution does it grant the federal government the
right to fight an undeclared preemptive war like the present Iraqi war.

The optimum number of turns depends upon the band. Such a balun optimized
for 160m may not be effective on 10m and vice versa. OTOH, ferrite baluns
can be designed to function over a 10:1 frequency range by the proper
choice of the material for the toroid.

make the wire a bit longer at each end,
then wind the extra into a coil.
You can stretch or compress the coil to tune the ant then secure it with
plastic wrap tags to hold.

Don't know what this means...? "...eventually become to short..." you
mean too short from all the bending and breakge from the many adjustments
you had to make over time ??

"Fix this"? Fix what?
Not sure just what you are asking, but...
My 40M dipole (inverted Vee) has the last two feet of wire wraped back up
the wire, inward toard the center. I just put the wire through the end
insulator and bring it back along the dipole and wrap it around to hold it
on place. No tape, just wrap it tight enough to hold itself. I adjust the
min SWR frequency that way. BTW, it is insulated wire.

Summarizing the other two posts and what you alredy know. With the effects of the surroundings the formulas won't be much good anyway.

Put the traps at the ends of the standard 75M dipole [["75m portion ...is easy ..."]]. Make this a little long if U like. Add a little too much wire for the 160, then measure the 75M and 160M min SWR freq. Adjust the 75M length for your 75M freq of interest. Then, using 468/F figure out how far off you appear to be on the 160 length. Trim off about 80% of that value, then trim-by-SWR the rest of the way.

Sound good fellas?

I usually cut the dipole several feet too long, run the end through the insulator, then tie the end back to the wire using a copper "split nut". I can then tune the antenna to resonance by loosening the split nut and moving the ends as required.

Thank you. I will try all of your suggestions. I did forget to mention that I am using a phono premp, which has a grounding lug on it for the phono. The phono IS rather old and so requires the use of a preamp. The phono and the preamp AC adapter are plugged into the same wall socket via a 3-socket extension cord, away from all other electrical equipment except the computer.

It just struck me as odd that I'm suddenly having this problem now. I had this setup working fine for over a week and now this. I did not unplug/replug any connections or move any of the equipment. I know it's not the radio station's problem but I was hoping they might at least try to explain to me what to do. Oh, well.

James

Is there a recognised way to connect a radio that just has a
telescopic aerial to a coax cable so that an external aerial can be
used?

If not, has anyone got any 'Heath Robinson' ideas?

Thanks

>Is there a recognised way to connect a radio that just has a telescopic aerial
to a coax cable so that an external aerial can be used?

Sure, just connect a short jumper from the center conductor of the coax to the
telescopic antenna.
What is a 'Heath Robinson' idea? Is that something desirable?

Message-ID: <cm9a6v$2j3$1@hercules.btinternet.com>
Source record: 87266

From MY copy of the message I sent containing the binary attachment I get no response by clicking the program's icon or the 'paper clip'.

I get a message which says "Outlook Express has made the attachment inaccessible". So its in my computer somewhere but I can't get at it. Not that I want it.

At some time in the distant past I may have set OE to reject suspicious non-standard attachments.

But out of curiosity, has anyone managed to download program SELFRES2 ?

Or has it been rejected simply because its a binary file sent via a newsgroup?

Thank you for your cooperation.

Although the program is finished I am reluctant to make it generally available via my website because it has not been tested against actual coils for spurious responses in impedance resonant curves which might restrict the operating bandwidth at the higher frequencies. It's unexpected defects in the coils I am interested in rather than defects in the program.

Reg,

I downloaded and launched the program without difficulty.

It is generally considered "unsafe" to pass around naked 'exe' files in newsgroups. It is quite typical that newsreaders have a default to disallow such files. I have also seen downloads of 'exe' files that came through corrupted for some reason. I do not know why.

In any case the difficulty with bare 'exe' files is one reason that many files are zipped up.

73,
Gene
W4SZ

(This group is set up as a non-binary group. However, there is no mechanism that prevent binary attachments, so that would not be the cause of the problem you report.)

Hi, Reg -

I am using XP. The attachment is grayed out in OE for me and is not
available. I have heard that M$ did that intentionally to minimize the
transmission of virii. If you simply rename the file extension to something
else, like SelfRes2.run perhaps, the file might then become available and
could be executed after renaming. Or you could just zip it up and it will
transfer okay.

I think. That's what I've heard, anyway.

John

Well, the Brits were still a bit pissed over that unpleasant business that ended in 1783, and then we did invade Canada. Certainly, by 1861, many Brits sympathized with the Confederacy out of spite.

What you gloss over is that Iraq in 1991 never really was contrite over invading Kuwait and getting their asses kicked out. We let them off far too easy, and their bellicosity festered for the next ten years.

Shocking as it may be, Congress can vote to obliterate half the planet, and it would be legal (by our system). Our Congress has authorized our President to take certain measures aimed at the punishment and eradication of global terrorists; ergo, he is acting legally, within the bounds of our Constitution.

Feel free to file a legal appeal (should you prove to have standing), or appeal to our sense of fairness. Otherwise, continue to bitch and moan and raise specious arguments.

Update...

In XP, I clicked Tools/Options then selected the Security tab. Unchecked the
"Do not allow attachments to be saved or opened...". I can get the file now.
I runs just fine.

Geez, maybe we would have reminded them about the Falklands? Really Peter,
that's a stupid premise.

Despite the fact that we were "invited" to intervene (just like the bleeding
hearts want "intervention" in Sudan now), we should have let Grenada rot in
place. For a very tiny shithole, I'm sure we have paid many times over in
cumulative aid and reconstruction. And of course, Grenada is now the jewel
of the Caribbean.

I personally never saw ferrite any finer than a vaguely gritty powder, and we had no need for anything finer in the technical ceramics that we were making. But the ferrite paints are a good example that finer grinding is common.

I think you are right about the smaller particles yielding high saturation levels. And another possible source for ferrite in powdered form might be Steward (in Tennessee).

Running win 98 here. The file is grayed out but this hapens alot to me. I tell OUtlook Express ro forward the message and from there I can run and or save the program just fine. Thanks for the many fine programs.

Have a 6 meter yagi (the 7 El. M Squared), and modeled it - the pattern gain,front/back ratio, E & H Degs., were way off from those claimed- at 50 MHz. Upon reconsideration, changed freq to 49 MHz, and VIOLA, got the expected gain, ect ! I then shortened the elements by 2/3 of the boom diameter- then it seemed to meet the claimed gain, ect. at 50.5 MHz ! Changed that to 3/4 the boom dia. and then , got claimed gain, ect., where it should be. My question is : It is my understanding that this is correct for calculating (or building ) antennas , with elements THRU THE BOOM, but this antenna has the elements supported on TOP OF THE BOOM ! Am curious as to what is going on (what am I missing)? any ideas ? Just curious-- Jim NN7K

> [[personally, i think if ur <2:1 makes no diff at the other end]]]
> --
> Steve N, K,9;d, c. i My email has no u's.

That's basically what I did. I ran into an interesting issue tuning
the 75m portion - as I cut the antenna in shorter and shorter
increments as I approached my design freq, something wierd
happened - I was at 3.844 and cut 12" off each end which got
me 3.868. I cut another 6" and got 3.860? At that point I stopped
cutting. My traps were designed for 3.890 but I had no way to
measure them.

Why did trimming 6" lower my resonant freq 8 kHz? I'm guessing
but could my traps be closer to 3.86 than 3.89? I'm afraid to cut
more.

Here are the results I got:

Band 2:1 SWR range Bandwidth Center Best SWR
160 1.862-2.040 0.178 1.951.0 1.0:1
80 3.759-3.916 0.157 3.837.5 1.0:1

Source record: 87178

Adding a boom of any diameter to a model as a single wire or series-connected single wires won't have any effect on results in EZNEC or similar programs, if it's placed exactly symmetrically with respect to the elements (the usual case). This is because of the simplified model of a wire and its current used by these programs. So the model has to be modified in order to account for the real-life effect of a boom (or clamps).

According to Lawson, in _Yagi Antenna Design_ (p. 7-11), when an element goes through a boom, the element should be lengthened by about 0.7 times the diameter of the boom in order to maintain optimum length. This means that the boom effectively shortens the element, and the model element should be made shorter by that amount. This is from an NBS report where measurements were made of actual Yagis. The report is available at http://www.boulder.nist.gov/timefreq/general/pdf/451.pdf.

Lawson also says that when an element is on the boom but not through it, "the element length should be increased by only six percent of the boom diameter; this small correction rapidly disappears as the element is spaced away from the boom (even by a small amount)." (p. 7-12)

Leeson details modeling requirements for a number of different clamping methods in Chapter 9 of _Physical Design of Yagi Antennas_. You haven't mentioned what sort of clamping system is used, and perhaps it's the presence of the clamp that makes the difference. I recommend taking a look at Leeson's analysis. Both Lawson's and Leeson's books are available from the ARRL.

It seems all ferrite shapes are made from the fine powder.
I wanted some to put as a 'goop' on some coax to make
a choke balun. There are various grades - mine was 15000u.
(IIRC)

It is very fine indeed. There is some in the modern
toners for the cheap laser printers and copiers.
It replaces the 'developer' of yesteryear.
In fact I had a lot of the old toner and after some
experimenting came up with a brew of ferrite/toner
good enough to use in the copier here :-)

Try some toner with a magnet - it sticks if there
is ferrite in there.

Know my reader? You must be kidding....I don't have *readers*....Or at
least, none of them have sent me a subscription yet...If you want me
to tailor my posts to a certain type of simple minded dumbass, you
will have to pay me.

> [ Keep It Simple And Practical ! ]

My PVC version can't get too much simplier...
>
> REMEMBER: What Works... WORKS ! { No Theory Required }

I'm sorry. I am not going through life as a crash test dummy....If you want to, be my guest. Remember! I didn't write the *thesis* as he called it. I just commented to the smartass that complained about it. If you don't want to read something, no one is holding a gun to your head. I find Telleys remarks about *censorship* on the shortwave NG to be really offensive. It ain't *his* NG. After reading his last two posts, I find *him* equally offensive. Only a childish asshole has to make up names for people he can't agree with. I'm glad the goofy bastard "plonked" me. He's obviously a smartass that wants to control how other people think or act on *his* shortwave NG. That was not the first time I'd seen him make smartass comments about RRAA for no good reason either...I live on both groups, although I don't normally crosspost, so I considered his comments to include me. MK

Hummmm. Maybe so. I received an antenna design today in an e-mail. It sure brings back memories of early fractal adventures I've heard described. I suspect this antenna will be a huge hit among the simple types who want an antenna that is easy to erect, but don't care how, or if, it actually works according to plan. The antenna was designed by KG5RQ, hence the name...No, it is not a slur against *the* G5RQ in England, whoever he may be... MK

> Which description is right?

Both should be right. If you vary the size of the coil in diameter,
you will need to change the number of turns. Think of a coil on a
mobile whip antenna. A big fat coil 4 inches diameter will need less
turns of wire to tune a certain freq, than a smaller 2 inch dia form.

Or does either have advantages and drawbacks?

Not sure...I would probably prefer the larger coil, if I had a choice,
but I don't know if there is really a large difference as long as both
are tuned properly. MK

>on (what am I missing)? any ideas ?

Adding a metallic boom anywhere close to an element will shorten its
effective electrical length. The same applies to various kinds of
metallic mounting plates and clamps.

Before you model a yagi, you have to change all the element lengths that
you input to the program - in order to input the correct electrical
length, you must *subtract* the boom effect from each physical element
length.

In the reverse direction, if you want to build a yagi from a model, you
must either use a non-conducting boom, or else make your choice of
metallic boom diameter and mounting method, and then *add* an
appropriate correction to each element length.

This is exactly what M-Squared will have done, to develop their yagi
from a model... if you ask nicely, they might tell you the correction
they used, or even supply the NEC file.

This boom correction is not a simple fraction of the boom diameter.
There are a variety of formulas, and the ones for most forms of VHF/UHF
yagi construction are summarized at:
http://www.ifwtech.co.uk/g3sek/diy-yagi/

# 1694. CATV splitter question

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-03 10:04:53 UTC
From: Jerry <jerry@nolikeyspam.com>
Message-ID: <4188AD44.3131@nolikeyspam.com>
Source record: 87189
Cross-posted to: rec.radio.amateur.antenna,rec.video.cable-tv,comp.home.automation

A question from a lay person. I'm looking for information on what kind of CATV splitter to buy. I have Time-Warner analog CATV and don't use any cable box. All my devices use coaxial RF cable as input. Here's my setup...

Cable comes into my house's outside junction box into a 4-way splitter with each output saying 7dB (whatever that means), then goes to four rooms.

Room 1: Bedroom without any TV. Coax not terminated.

Room 2: Office with cable modem and TV. Cable company used a 2-way splitter with each output saying 3.5dB.

Room 3: Bedroom with a TV.

Room 4: My main media room. Here's where I need the right coax splitter. I currently have a 2-way splitter connected to a VCR and a TiVo. I'd like to add a DVD recorder with a cable-ready tuner. All 3 devices would have coaxial RF cable input.

My two questions:

1. Should I get a 4-way coax splitter with each output at 7dB and terminate the unused output? This would leave an output free for future expansion in Room 4. I saw such a splitter at Radio Shack. Is there a better brand?

2. Should I terminate the cable in the unused Room 1?

Thanks for any suggestions.

Jerry

Generally the splitters are installed by "professionals" without even considering termination of the unused ports. I normally put the splitters closest to the main feed line coming into the residence. use high quality coax (RG-6) and high quality crimped connectors. Termination at the unused ports with a 75 ohm terminator available at most supply outlets and occasionally Rat Shack. The I take a nice portable tele to each final location, check the quality of the supplied signal at that point, if necessary, installation of a high quality distribution amplifier rather than the passive splitter in required. May want to contact a person who does this ona commercial basis and askk theire source of materials, etc.

# 1697. Ground rod or water pipe?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-03 11:16:53 UTC
From: Ruben Undheim <saltmakrell@hotmail.com>
Message-ID: <4188cc35$1@news.wineasy.se>
Source record: 87194

Hello

I have my shack on the second floor, about 8 meters above ground. I am going to use a dipole antenna for 20M
Should I use the water pipe system as ground, or should I use a thick wire on the housewall down to a ground rod?
I fear that the wire down to the ground rod may emit unwanted RF (have read that somewhere).

Regards
Ruben

# 1698. Re: Current in loading coil, EZNEC - helix

Cec sez,

> My solution is to get Reg to write a new program. :-)
>
=====================================

My patience is wearing thin.

Nevertheless, once more into the breach.

There's no need to write a new program. There's not even any need for an old one.

Knowledge of the current distribution along a loading coil has no practical use except to assist with drawing pictures of it in books and magazines.

FOR PRESENT PURPOSES THE LENGTH AND IMPEDANCE OF THE ANTENNA BELOW THE COIL IS NOT RELEVANT. IT CAN BE CONSIDERED TO BE PART OF THE GENERATOR.

LET THE ANGULAR LENGTH OF THE COIL = THETA DEGREES. OTHERWISE KNOWN AS THE PHASE SHIFT. THIS IS A FIXED, IMMUTABLE QUANTITY SET BY THE PROPAGATION VELOCITY = 1 / SQRT( L * C ).

THE MAGNITUDE OF THE CURRENT DISTRIBUTION ALONG THE COIL IS ALWAYS THE SAME COSINE CURVE BUT WHICH IS TRUNCATED (SLICED OFF) AT VARYING ANGULAR DEGREES AT EITHER OR BOTH ENDS.

THE ANGLE AT WHICH THE TOP END IS TRUNCATED DEPENDS ON THE INPUT IMPEDANCE OF THE ANTENNA ABOVE IT. IT IS ALSO RELATED TO Zo OF THE COIL WHICH IS THE USUAL SQRT( L / C ).

THE ANGLE AT WHICH THE BOTTOM END IS TRUNCATED IS ALWAYS THE TOP ANGLE MINUS THETA. IT CANNOT BE ANYTHING ELSE.

THUS, WHEN THE TOP END IS OPEN CIRCUIT AND THETA = 90 DEGREES WE HAVE A COMPLETE 1/4-CYCLE OF A COSINE CURVE - A 1/4-WAVE RESONANT HELICAL ANTENNA.

The foregoing applies to both short, fat coils and long, thin coils, close-wound or stretched-out.

Coil resistance is the uniformly-distributed radiation resistance plus conductor resistance.

For useful calculations such as Q, bandwidth, efficiency, etc., you can forget all about bewildering reflections, standing waves, forward and reflected power and use the well-known classical transmission line formulae, the everyday tools of all good engineers.
The final wanted characteristic, the radiation pattern, can be found with

number-crunching EZNEC-type computer programs which work in an entirely
different manner.

Reg Says:
>
>Knowledge of the current distribution along a loading coil has no practical
>use except to assist with drawing pictures of it in books and magazines.

WROOOONG!

Have you ever tried antenna shootouts? Cecil can enlighten you about the
difference in efficiency and signal levels radiated by various configurations
(bottom, center, top loading).
The efficiency is proportional to the AREA under the current curve on the
loaded radiator. That is dependent on the position of the loading element
within the radiator. That also depends on the current distribution (drop :-)
across the coil. Use that in the loaded parasitic element beams and the effect
is magnified.
So obvious, but hard to swallow for Rauchians?

Viva Bush!!! Sayonara sKerry botoxed flipflopping lying girlie man.

Hello Johann:

Loose the coax Balun, and get a toroid balun.

All the coax Baluns I have used are now used to tie up bushs for pick up
on Thrusdays morning trash pick up.

http://www.amidoncorp.com/aai_cost_baluns.htm

After replacing the coax balun, with the Amodon 1 to 1 HBH50 current
type balun, on my yagi beams it was like night and day. Ten-4.

If you're really interested in the "AREA under the current curve,"
you'll have to figure out how to make an efficient, continuously loaded,
short antenna. You'll find, though, that the difference between a
continuously loaded antenna and an antenna with the loading coil,
say, halfway up from the feedpoint won't amount to a hill of beans.
There's still no such thing as a "current drop."

For a guy who is always excoriating people for believing old wives
tales, you've just told a whopper, Reg. It's true, you might get an
answer using the above theory that is "good enough for who it's for,"
but as an expression of what's actually happening in the antenna, it's
hopelessly simplistic.

# 1707. 80/160 trap dipole question - last one I hope

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-03 14:19:48 UTC
From: Ken Bessler <kg0wx@NOSPAMyahoo.com>
Message-ID: <tN5id.41424$lp6.2321@okepread01>
Source record: 87202

One leg of my trap dipole ran nice and high between two trees, The other ran to a telephone pole but in the process of installation, it caught halfway on a roof tile and ended up with the trap about 13 feet high. The other trap is about 30' up.

I fixed the situation and now both traps are even. It had interesting results:

160m resonant freq went up 50 kHz.
75m resonant freq went up 75 kHz
2:1 swr bandwidth on 160 got smaller by 20%
2:1 swr bandwidth on 75 got larger by 10%

Am I correct in assuming that the smaller b/w on 160 indicates better efficiancy via higher Q? It already works pretty good, I made a dozen contacts out to about 800 miles on 1975 last night with 50w and that was with the east trap @ 13'. I don't know really how good that is but everyone I talked to was impressed at how good I was getting out with "a trap dipole and only 50w".

read
> that somewhere).

Hi Ruben, sounds like three stories above ground, two stories would be 4 meters even if a 1 meter+ raised foundation was included. At any rate, a dipole is a complete antenna that does not use an RF ground or counterpoise. Transceiver mismatches will place high SWR on the feedline, not an RF ground should you install one anyway. If you later add some kind of longwire or other voltage-fed antenna then an RF ground would be important. You could use 12" wide 20 ga copper flashing (available at roofing companies) to make a workable ground from your elevated shack location. Anything less would have incredibly high impedance due to the distance to earth ground. Your dipole antenna feedline should enter the building at ground level, and the coax shield should be grounded there before coming "up" into the shack. There will remain a high potential between your shack equipment and the earth ground no matter what kind of ground you attempt at that height. The 12" wide copper strap connection would just be the lowest potential you could achieve, water piping or any solid wire size would not even come close.

Best regards,

Jack Painter

Cecil:

Your editing is commendable, but your memory is short. This thread started with the justification of force as valid due to Sadaam threatening our national interests (Kuwait & Saudi oil). The fact that he was a looney, playing six sides against the middle and balancing violent fanatics of multiple flavors, didn't help, but that alone wasn't the primary reason. (And I'm sure that in the realpolitick of Iraq, Sadaam alternately used, funded and sought to exterminate Al Quaida.)

We should, by all means, use diplomacy and incentives, but they seem to have not worked very well when Sadaam announced that Kuwait was the newest province of Iraq.

One device input for cable (the DVD) can feed all other devices, including surround sound theatre system when you later add that. If for some reason you want to record separate events simultaneously, then you could use a passive splitter between the DVD cable output and the VCR. If not, an AB switch between VCR and TiVo would work fine.

**********
Yes & no...if the splitter is a 1 gig splitter, it'll work. Don't use the 900mhz splitters...they'll work...so so...but you'll get better signal through the 1 gig splitter, and they are not expensive...I get them at Home Despots...about $5...can't remember if they are Ideal or RCA branded...you will probably not need any signal amps...unless your really working with a bad cable company. They take special care to boost their signal throughout their network, and really try hard (in my area with Comcast) to pump good signal to their users.
**********
> 2. Should I terminate the cable in the unused Room 1?
**********
Always terminate unused coax ends tied to the distribution network.

Everything you get you have to pay for. "Getting" Hussein wasn't
really worth the money, lives, and loss of international good will
we expended getting him. Moreover, now that we've got him, what are
we going to do next? Where are we going to get the troops to
pacify Iraq and turn it into a compliant, friendly, little
police state like Saudi Arabia? When are we going to see the price
of gasoline and heating oil drop? Where's the reward?

Reg, G4FGQ wrote:
"For present purposes the length and impedance of the antenna below the coil is not relevant. It can be part of the generator."

I infer that Reg is saying that at a particular frequency, a loading coil has a unique voltage across and a unique current through it.

Probably sometimes so, but the simple argument was that the current at the coil ends can be different. This is caused by superposition of forward and reflected waves. The same power may have any number of voltage to current ratios (impedances). The purpose of a loading coil is to transform an antenna impedance to an impedance more compatible with a radio. There is a difference in impedance between the ends of a loading coil so that the current at its ends are different.

The length and impedance of the antenna below the coil participate in the imbalance seen at opposite ends of the loading coil. The height of the loading coil on an antenna is thus significant.

The length and impedance of the antenna below the coil participates in radiation. The function of a transmission line is to convey energy. The function of an antenna is to radiate energy.

Radiation is a function of unbalanced current and the length through which it travels (page 864, Terman`s 1955 edition). The current per unit length below a loading coil is higher than above the coil. More radiation per unit length results from more current. This affects impedance at the coil ends.

"For present purposes" we may declare anything so long as we don`t define our purposes, but Fig 9-22 on page 9-15 of ON4UN`s "Low-Band DXing" is significant and no one has said his pictures are wrong and given reasons.

Best regards, Richard Harrison, KB5WZI

>
====================================
```

One of the advantages of a dipole antenna is that it doesn't need a ground connection. There's nowhere to connect one.

The transmtter does need a ground and it usually obtains one from the domestic 110-volt power socket.

But a much better ground can be obtained from the nearest domestic metal water pipe or central heating system which eventually finds its way to the incoming water main.

Two separate well-spaced ground connections, running in different directions from the transmiter to different parts of the plumbing system are better still. There is usually a threaded bolt with a wing nut at the rear of the transmitter for connecting to ground wires.

A wire down the wall to a single ground rod makes a very poor ground. It is worse than the connection to the 110-volt power socket. The rod is no better than a shallow buried wire of about the same length. It is only of use when there's nothing else available.

Grounding wires need be no larger than 16 or 12 gauge. Think in terms of mechanical durability and reliability.

All wires in the vicinity of a transmitting antenna pick up and re-radiate energy or transfer it somewhere else. It is of low level, usually imperceptible and nothing to worry about.

Only when connected directly to an antenna to form part of the radiating system will relatively large amounts of power find its way along wires to where its not wanted. Something is usually seriously wrong if you should get small harmless burns on the lips when using the microphone with a Tx power of 100 watts or less.

There are a score of different ways in which things can happen. All are curable. Most likely you will never be afflicted. No need to do anything

until something actually occurs.

It's very rare for earth wires to re-radiate anything that is harmful or interferes with anything or is even detectable. Since 99 percent of radiation comes from the antenna that's where most of the interference in or around your house originates - if you should get any.

That 7db label means that the splitter is reducing the signal by 7db. As you add more splitters down the line you further reduce the signal. Try the 4 port splitter and see how your picture looks. At that point you'll have a 14db signal loss but if the picture is good that's all the counts. If it's grainy you may need to use a 4 port drop amp. You can get good ones (Electrohome, Scientific Atlanta, etc) on ebay for about $20.

I wrote that you'd have to make an _efficient_, continuously loaded,
short antenna if you want to get the most area under the curve. That's
easier said than done. Certainly, you can't do it.
So a shootout is your idea of a reliable
antenna test. I guess it's no worse than using fish tank
thermometers to measure efficiency.

## 1721. 32 ft end tuned vertical or??

Newsgroup: rec.radio.amateur.antenna

Hi all...
I have a 32 ft aluminum mast that I want to feed at the bottom with an extensive radial system laying on or just below the ground.
I plan on homebrewing a matching network at the base, with tuning stubbs on the vertical radiator and plan to use the antenna on 30 thru 10 meters.
Before I get too into the project, I am wondering if I would have a better antenna if I simply purchase a Gap Titan, butternut or something of their irk. Thanks in advance.

Hi Ruben,

The water pipe is better, a ground rod is OK. For a balanced system,
ground's only use is for AC safety (to protect YOU).

>I fear that the wire down to the ground rod may emit unwanted RF (have read
>that somewhere).

As you are using a dipole, this unwanted radiation will occur only if
it is unbalanced. The radiation comes from "Common Mode" current.
"Common Mode" current is the difference in the two currents in each
half of the system that is unbalanced. Dipoles are balanced designs,
but not always balanced installations.

How can you tell when you have an unbalanced system? This is not
easy, OR if it is easy, it is a real problem.

One SWR reading does NOT indicate an unbalanced system. One SWR
reading does NOT indicate a balanced system.

The most obvious sign of "Common Mode" current occurs when your
transmitter acts odd by being difficult to tune, folding back its
power, or you can actually feel the sensation of current on bare metal
(like connector shells or a chassis). A minor sign of "Common Mode"
current is receiving signals on your dipole that should be in its
null. This last sign may even be a preferred condition, thus subtler
signs may go unnoticed.

What this means is that "Common Mode," or system unbalance, or ground
wire radiation may not be a problem even if it exists.

Yep, I previously guessed the SQRT(L/C) would be very high for a large coil.
After using your Solonoid program, it seems my guess was much too high. The
Z0 of the coil seems to be more like 1k-2k than the 10k I first guessed.

Hi Jerry,

Sounds fine. Better brand? Probably not (in other words, same
chinese product with a different label).

>2. Should I terminate the cable in the unused Room 1?

Only if your picture appears to be fuzzy or distorted; however, it is
a simple matter to perform and doing it tends toward a better
solution. If you do, you should also terminate the unused splitter
output too.

> Cable comes into my house's outside junction box into a 4-way splitter
> with each output saying 7dB (whatever that means), then goes to four
> rooms.

Usually that "7dB" means the output has 7dB less signal strength than the input. In this context, 3dB down means one-half (1/2) the signal, so 7dB means 1dB less than 1/4 the signal. In an ideal 4-way splitter, each output would have 1/4 the signal, so your splitter has some 1db additional real-world loss (expected, and 1db is OK, 1.5db is bad).

To overcome loss and signal division, you might need to add a distribution amplifier before the first splitter in the junction box. Usually a cable company will install one, especially if using a cable modem. This is usually a box with a cable in, cable out, and a cable connected to a power adapter. Sometimes you can get an amplifier combined with a splitter. I don't like those.

In addition to a loss specification, the bandwidth of the splitter (or amplifier) is often specified. For satellite and digital cable, and my preference in all installs, are splitters with a bandwidth up to at least 1ghz.

> Room 1: Bedroom without any TV. Coax not terminated.
>
> Room 2: Office with cable modem and TV. Cable company used a 2-way
> splitter with each output saying 3.5dB.

That splitter shows that each output gets a little less than 1/2 the input signal, or less than 1/8 of the original signal (1/4 divided by 2).

> Room 3: Bedroom with a TV.
>
> Room 4: My main media room. Here's where I need the right coax splitter.
> I currently have a 2-way splitter connected to a VCR and a TiVo. I'd
> like to add a DVD recorder with a cable-ready tuner. All 3 devices would

>
> My two questions:
>
> 1. Should I get a 4-way coax splitter with each output at 7dB and
> terminate the unused output? This would leave an output free for future
> expansion in Room 4.

A 4-way splitter would cut signal strength in half to each of the devices currently connected to the 2-way (from 1/8 to 1/16).

A 3-way splitter (or two of them) would give a slightly stronger signal if used instead of the four-ways. Splitters are also available in 6-way and on up. Just a bit harder to find. :) I've had good results with the high-grade (low loss, wide bandwidth) splitters from MCM Electronics.

Can you run any additional coax from the junction box to the various rooms? My preference would be to disconnect (at the junction box) Room 1 (since it isn't used) and run that output via a new line to Room 4.

Now with 1/2 the available signal in room 4, you can run 1/8 1/8 1/4 to three devices, or add a 2-way splitter and run 1/8 1/8 1/8 1/8 to four. Or you could replace the splitter in the junction box with a bigger number of outputs and that way everything would have equal signal.

If you ever have cable modem problems with signal strength, you could either run a second line to room 2 (one for each device) or else use a 2-way splitter at the junction box before the 4-way, connecting the 4-way to one output (1/2 the signal) and the room 2 line to the other (1/2 the signal to room 2, where it gets split so each device gets 1/4 instead of the current 1/8).

> 2. Should I terminate the cable in the unused Room 1?

In theory, all unused outputs should be terminated. It might or might not make any noticable difference.

>irk. Thanks in advance.

Not particularly, except maybe for the higher frequencies. Your 10M
of radiator being used on a 10M wavelength portends difficult tune up
(perhaps part of your motivation for the matching box). However,
being one wave long, it also has major radiation lobes pointing up
rather than out.

It is most suited for 40M (quarterwave) through roughly 15M (5/8'ths).

> say, halfway up from the feedpoint won't amount to a hill of beans.

Wrong! Bragging rights after a 75m shootout are worth a lot more
than a hill of beans. A helical antenna has NEVER beaten a center-
loaded antenna in a 75m shootout. And in fact, my junk box *top-
loaded* antenna beat all the center-loaded bugcatchers in one of
the CA shootouts. The current below the coil is the highest current
in the average 75m mobile antenna. The longer that uninhibited
section is, the stronger the radiated signal, thus my success in
the shootout. My bottom section was about ten feet long, then a
horizontal coil and horizontal top hat. I'm going to refine that
configuration when I get time.

> There's still no such thing as a "current drop."

The decrease (drop) in current across a loading coil installed in
a standing-wave antenna does NOT in any way violate Kirchhoff's current
law. One can imply from Kirchhoff's current law that there is no current
decrease (drop) across a point. I don't know anyone who disagrees with
that so any argument is just a straw man. Kirchhoff never said the
current at one point in a network had to equal the current at another
point in the network.

Many patches have been added to the DC circuit model to try to adapt
it to RF networks. Some function after a fashion and some fail utterly.
We all need to be able to recognize the difference. For EM waves, the
E-field and H-field are often affected in the same way. Saying that
the E-field voltage drops but the H-field current doesn't drop is
simply nonsense. Likewise, saying that the H-field current flows and
the E-field voltage doesn't flow is nonsense. The E-field and H-field
are usually inseparable.

For this discussion, the magnitude of radiation is irrelevant except
as it relates to "losses" from the system. So please enlighten us as
to "what's actually happening" to the standing-wave current "in the
antenna".

> The water pipe is better, a ground rod is OK. For a balanced system,
> ground's only use is for AC safety (to protect YOU).

About the worst advice ever given, offering a water pipe in a second or third story structure as an AC safety ground. First, unless you can verify that the cold water supply in your structure is a bonded grounding electrode conductor (and it probably is not), it must not be used for any kind of electrical safety connection. Secondly, the AC circuit breakers that are designed to protect your life by limiting the time-frame of a current overload or neutral-sensing return voltage deficit cannot do so if you modify the circuit path. This is dangerous even if the ground is as poor as you would achieve from the elevated potential of your second or third story flat. Only the bonding of all shack equipment, at least some of which would be directly connected to the AC mains would provide additional electrical safety. Grounding does NOT provide electrical safety, bonding does. It was a typical "unbalanced amateur's response" to tell you otherwise. In an equipment fault event, you could easily be killed by the current diverted to a separate station ground if the equipment was not properly bonded first.

Best regards,

Jack Painter

Whoa there, Ed. Kuwait was once part of Iraq. Like the Damned Yankees
fought to re-annex Texas (even though Texas had the legal right to
secede) Sadaam was fighting to re-annex Kuwait. The winners get to
write the history. If the Confederacy had won the war, Lincoln would
probably have gone down in Confederate history as a terrorist.

And the fact remains - we waited much too long to do something about
Sadaam. The statue of limitations had run out on the Kuwaiti invasion.
That oversight stuck in the gut of Bush #41 and therefore stuck in
the gut of Bush #43. IMO, it was more *personal* revenge against Sadaam
than any real threat to the USA. P.S. I didn't vote for Kerry either -
I voted Libertarian. The Libertarian presidential candidate promised
to bring all of our troops back to the USA where they can perform their
constitutional duties.

That means that the RF signal level at each output port is 7 dB below
the level being fed into the input. That's not too bad - a perfectly
lossless 4-port splitter would divide the power four ways, resulting
in an output level at each port which was 6 dB below the input level.
This splitter has 1 dB of additional loss.

>Room 2: Office with cable modem and TV. Cable company used a 2-way
>splitter with each output saying 3.5dB.

Again, that's not too bad - 3 dB of reduction per port (50% of the
power going each way), plus an additional .5 dB of loss in line with
each port.

This means that your TV and cable modem are seeing signal levels 10.5
dB below the level that your cable company is feeding your house.

>Room 3: Bedroom with a TV.

>expansion in Room 4. I saw such a splitter at Radio Shack. Is there a
>better brand?

You could do that. You'll be wasting some of the RF power fed to that room, into the termination resistor on the fourth port.

Or, you could daisy-chain an additional 3.5 dB splitter off of one of the two ports on the existing two-way splitter. This approach will give you three outputs, two of which have lower RF levels than the third. Use the third port (the one coming out of the first splitter) to feed whichever device seems to need the strongest signal for a decent picture.

>2. Should I terminate the cable in the unused Room 1?

Generally a good idea, for several reasons. RFI is one such reason... unterminated ports can "leak" RF, and some of the cable-TV channels overlap with amateur bands (e.g. 2 meter) and aircraft/public-safety bands. Cable companies are required to [try to] keep their cable plants leak-free, due to the interference that these cable channels can cause.

Richard Harrison wrote:
> There is a difference in impedance between the ends of a loading
> coil so that the current at its ends are different.

Good point, Richard. Why isn't anyone arguing that the current on each side of a loading coil in an antenna tuner is equal? It can easily be proven to be different using a Smith Chart.

> "For present purposes" we may declare anything so long as we don`t
> define our purposes, but Fig 9-22 on page 9-15 of ON4UN`s "Low-Band
> DXing" is significant and no one has said his pictures are wrong and
> given reasons.

I haven't seen that book, but I have seen reproductions of his diagrams on the net. The situation is not as simple as asserting that the coil occupies the number of degrees not occupied by the vertical sections. As usual, the facts lie somewhere in between the two rail arguments.

1. The currents at each end of the coil are not equal. (shoots down rail #1 argument)

2. The current distribution over the entire loaded mobile antenna is not a standing cosine wave. (shoots down rail #2 argument)

Since the coil is a different characteristic impedance than the vertical sections, there exist reflections, both ways, from each end of the coil. Taking four additional sets of reflections into account mathematically is extremely difficult. That's probably why nobody has ever attempted it.

However, a bugcatcher antenna can be approximated by the following:

---600 ohm feedline---+---1600 ohm feedline---+---600 ohm feedline---open
bottom section loading coil top section

By modeling with EZNEC, I am attempting to ascertain the VF of the loading coil. That's the only thing standing in the way of a conventional analysis.

Sorry, I thought the meaning was clear. The "magnitude of radiation is irrelevant" to the argument which is confined to current through a loading coil. You must be getting senile, Richard. You keep forgetting what the argument is all about. I trust that's not a deliberate diversion. :-)

It will make an excellent antenna for the bands Richard indicates: down
to 40m, and up to about 15m.

You do seem to be prepared to spend some money, so if you don't want to
run outside to change bands, a remote auto-ATU would be a very good buy.

That is exactly what I am using now - a 32ft mast with an auto-ATU at
the bottom. If you can tilt the mast over easily, you can also plug in a
horizontal loading wire at the top to make an inverted-L for 80m and
even 160m.

Did you throw it because of signal loss or because the coax balun did
not worked as expected, so what a balun (balanced <--> unbalanced) is
meant to be?

It's not all about that i really need a balun when running a dipole
antenna and rg58 but i fear RIF with neighbors ....

Thank you very much for your in depth explanaition. The program worked
just fine.

I am not a "hamer" but do CB-radio and the only thing which is legal
there is to play around with different antenna types. I am still
starting to get into the whole matter by reading books and info on the
internet.

> What do you get?

I get a self resonance frequency of 23MHz and ~ 9 kOhm @ 28MHz test
frequency. For CB radio this should be pretty much sufficient, though
now i would try to get resonance frequency closer to operation frequency.

Ed,

We didn't finish off Saddam simply because
it would have de-stabilized the area. Bush Sr.
advised Dubya not to invade for this reason...
advice which he chose to ignore for personal
political advantage (and Halliburton's gain).

As evil a tyrant as he was, Saddam kept the
fanatical Shiites suppressed. Dubya mindlessly
opened this Pandora's Box, as is evidenced by
the current situation there now. As much as
we'd like to believe otherwise, we cannot win
in Iraq unless we become as evil as Saddam.

Is this who we are to become?

Chuck

Tom, W8JI claimed such in the following quote from eHam.net:

"If you look at HOW an inductor works, the current flowing in
one terminal ALWAYS equals the current flowing out the other
terminal."

Maybe you should catch up on the argument before you expose your
ignorance of the argument any farther. Tom's above assertion is
what the argument was/is all about. Your posting proves that you
are ignorant of what the argument is all about.

> You guys sure go out of your way to pat yourselves on the back
> for proving something no one has ever argued about.

You are continuing to exhibit your ignorance. W8JI (your hero)
asserted the above quotation that the current flowing in one terminal
of an inductor "ALWAYS" equals the current flowing out the other
terminal. Are you going to back him up on that assertion or not?

Tom Rauch is the person who made the above assertion of which you
are obviously ignorant. Please alleviate your ignorance and get
back to us. Do you really believe that, for an inductor, "the current
flowing in one terminal ALWAYS equals the current flowing out
the other terminal"? It's a simple yes/no question and it's time
for you to $hit or get off the pot.

Not only that, can he defend this assertion of Tom Rauch in his
response to your posting on eHam.net?

"If you look at HOW an inductor works, the current flowing in one
terminal ALWAYS equals the current flowing out the other terminal."

Has the definition of "ALWAYS" changed while I wasn't looking?????

Thanks to everyone for all the good input.

Please tell me if the following would be the best solution. As mentioned in my first post, my Room 1 which currently has the CATV outlet unused, is adjacent to my main media room. Would it be best to run a coax from Room 1's unused outlet through the wall to my main media room and have no additional loss for one of my recording devices? Hugging the wall, that would be a 50 foot run. I'm not sure how much loss 50 feet of cable would create. Is RG-6 the best coax to run?

Also, I want to make the best choice for the existing 2-way split in the main media room. What's the difference between...

- 1GHz 90dB 2-Way F-Pin Splitter
- 1GHz 130dB 2-Way F-Pin Splitter
- 2GHz 90dB 2-Way F-Pin Splitter DC Passing

I saw these at
http://www.national-tech.com/catalog/fcoaxialsplitters.htm

Thanks to you all, I'm learning.

Jerry

> antenna and rg58 but i fear RIF with neighbors ....

Hello Johann:

The Yagi beam antenna with the coax coil balun, showed very little change in SWR as compared to significant changes in the driven element lengths. Regardless to the amount of cussing, different type of coax coiled configurations and such, beer bottles thrown at the tower, or facing east produced a poor antenna pattern, and signal straight.

When the Amaidon 1 to 1 Current Balun was installed, this all went away. The SWR could now be changed by lengths in the driven and parasitic elements, the signal strength went to where is was supposed to, referenced to a dipole antenna, and the beams pattern sharpen up.

The coiled up coax balun, was allowing RF Energy to travel down the coax resulting in detuning the antenna significantly.

>"If you look at HOW an inductor works, the current flowing in one
>terminal ALWAYS equals the current flowing out the other terminal."

I think that is true. If you define current as electron flow, then the fields and radiation that a large coil may be subjected to, will not increase or decrease the number of electrons that the coil contains. As such, the amount of electrons entering the base of the coil, will equal the same number exiting the coil, with time displacement.
Consider a large physically long capcitor, with multiple plates. One can use this as a loading element. There is no electron flow between plates. However there is "displacement" current between the plates that has no physical meaning. Now what? The capacitor will be just affected as a coil.
So, from the conservation of electron flow I don't know what to believe.

DC passing would suggest that all these are rated for satellite TV
systems (hence the high frequency rating). The dB ratings are port
isolation (one side interfering with the other). Choose one with
highest number (either frequency or dB or both) in anticipation of
future needs - price is hardly an issue with these components.

|given reasons.

There are multiple editions of this book. Could you describe in more detail what the "pictures" are saying.

They are probably the same as in my third edition, just on different pages with different figure numbers.

I should wait for your answer, but I'm going out on a limb and guessing that they are the ones showing current distribution and "area under the curve."

If my guess is correct, then I submit that using them in the current context (no pun intended) is not applicable.

This whole "shootout" nonsense pertains to antennas with (unloaded) electrical lengths well under 0.1 lambda. Devoldere shows no examples of loaded antennas that are this short.

If I guessed wrong, then I will standby for clarification.

I think you've just proven that all antennas must have a constant
current distribution on their driven element... the same argument can
probably be made about a piece of straight wire!

More generally: I'd like to propose a thought experiment, which I
think may cause you to reconsider your conclusions.

The experiment: start with a straight length of wire 1/4 wavelength
long (minus a bit) at a frequency of interest. Install it over an
infinite ground plane and feed it at the base. You've got a resonant
"1/4 wavelength" monopole.

I think most people will agree that the net-current distribution in
said monopole is tolerably close to being a cosine function - highest
at the feedpoint, and lowest near the tip.

Mark two positions on the wire, 1/3 and 2/3 of the way along its
length. Consider the three sections of wire to be the "base", "mid",
and "tip" sections.

I think most people will agree that the net currents at the two ends
of the "mid" section are not equal. We haven't changed the
cosine-like current distribution by simply marking the third-of-the-
way points.

Now... take the "2/3" point, and pull it back (or down) towards the
base of the antenna, by some small amount... say, 1% of the length of
the "mid" section. Leave the "1/3" point right where it was. There's
now a small amount of slack in the "mid" wire. Shape the "mid"
section into a small-diameter helix, with uniform spacing between the
turns, so that the helixing of the wire just takes up the slack.

The antenna has now been shortened slightly, and some inductance has
been added to the "mid" section. Add or subtract wire at the end of
the "tip" to bring the antenna back into resonance.

Now... are the net currents at the "1/3" and "2/3" points suddenly
equal? Or, are they still unequal (but perhaps different from what

they were when the mid section was straight)? If unequal, by how much?

Now, continue repeating this process... pull the "2/3" point back towards the base by the same amount you did before (1% of the original length of the "mid" section), re-coil the "mid" section into a helix to take up the slack, adjust the length of the "tip" to re-resonate the antenna, and re-evaluate the net currents at the "1/3" and "2/3" points. You can do this "shorten and re-resonate" step a total of 100 times, at which point the "mid" section has no physical length and is a "pure" inductance. [Let me know what page you find it on in the Digi-Key catalog, please!]

You may use any strategy you wish for deciding how many turns are in the helix at each step, and what its diameter is at each step, as long as you're consistent and as long as all of the slack is used up each time.

So... we now have a total of 101 sets of measurements... all the way from "mid is a straight length of wire" to "mid is a pure inductance having no physical length". We could graph "difference in net current between points 1/3 and 2/3" on the Y axis, and "number of shortening steps taken" along the X axis.

Question: exactly how many shorten/re-coil/re-trim steps must we go through, before the net currents at the two ends of the mid-section / helix / coil become the same (mathematically identical, assuming zero resistance in the wire)?

Gary,

There is not the slightest bit of mystery in the "conservation of electron flow". An important relationship in electromagnetics is the so-called continuity equation. In simple terms this is an expansion of Kirchhoff's current law. It says that any current imbalance at a point in space must be compensated by a change in the stored charge at that point in space. You can see the exact equation in any mid-level text on E&M.

This is how capacitors work. Current flows in but does not pass through the gap between the plates. Instead, charge is stored on the plates. It is sometimes convenient to describe this behavior in terms of displacement current through the gap, but of course no electrons actually pass between the capacitor plates.

Antennas work the same way. Any change in current along the antenna must be accompanied by a change in stored charge. The antenna acts as a capacitor. Everyone talks about high voltage at the tips of a dipole antenna, but perhaps fewer people understand there is a buildup of stored charge as well.

You have to use some care in applying the conservation of charge to a system that includes radiation or other manifestations of displacement current. Imagine a capacitor with widely spaced plates. Charge flows into one plate of the capacitor, and an equal amount of charge flows out of the other plate. You have to include both plates in the system when counting up the total amount of charge that's conserved. Similarly, in the case of a radiating coil, you have to count the charge that flows on all nearby and distant conductors as a result of the (field created by) the charge flowing on the inductor. That is, some of the charge that flows into a radiating inductor flows out of other nearby and distant conductors.

In the absence of radiation, all the charge that flows into an inductor has to flow out, a point I and (much more eloquently) Ian and others have tried to make, but which is lost on some of the most vocal contributors to the newsgroup. This concept doesn't seem to fit neatly into some of the preconceived theories, so is simply being ignored. In the end, any theory that truly explains observed phenomena has to work with physically vanishingly small inductors, for which the currents in and out must be equal, as well as larger ones.

Port to port isolation is typically in the upper teens to mid twenties, depending on manufacturer and frequency. The 90 and 130dB you see in those specs (that appears to be about the only spec they give, in addition to bandwidth) is the RFI immunity. One of the specs they don't list is the return loss. Are the 90dB ones solder backed or epoxy? Are they made utilizing a PCB design, or are the components just soldered together and stuck in the housing?

Like Richard wrote, fork out the extra couple of bucks and get some real splitters. One good place to get some is <http://www.cencom94.com/gpage.html>. They're made by CATV industry manufacturers and used by cable companies. Holland is Comcast approved and PDI is widely used by Time Warner.

Most cable systems are designed to provide 15-20dBmV at the tap, which equates to about 10-15dBmV at the groundblock. For safety's sake, use the lower number in your calculations.

As you've seen and others have written, a 4-way splitter loses ~7dB on each leg. The actual loss varies with the frequency. The 7dB is at 50MHz. In the 550-1000MHz bandwidth, it goes up to 8dB. Since the higher frequencies have more loss through both the cable and the passives (splitters), calculate using the loss at the high end of the spectrum, which is 5-750MHz.

10dBmV going into a 4-way splitter has (10-8=) 2dBmV at each port to go out to each outlet. RG 6 loses ~5.8dB per 100' (@750MHz), so an outlet that's 50' from the splitter loses ~2.9dB in the cable. You had only 2dBmV to begin with and the cable is attenuating it another 2.9dB, which means that you're going to have a signal level of -0.9dBmV at the outlet. Throw in another 4 for a 2-way splitter, and you're down to -4.9dBmV. Time Warner may run their systems with 20dBmV at the tap, which would, so go ahead and add 5 to the above numbers if you want. But that still leaves you with only +0.1dBmV at a 2-way splitter.

A pretty good rule of thumb is that if there are more than 3 outlets, use a 15dB gain amplifier.

Always terminate unused outlets and ports on a splitter. There's ingress and reflections to worry about.

As someone with well over 10000 customers, I can assure you that Richard
is correct.

There was also announced today, an exploit that doesn't even need you to
click on it if you run, gasp!, Microsoft clients.

Here is the link to the story-

http://software.silicon.com/security/0,39024655,39125549,00.htm

and here is a link to the slashdot discussion of it -

http://it.slashdot.org/article.pl?sid=04/11/03/1829252&tid=172&tid=201&tid=218

I also have to admit that the exploit needs a dummy on the receiving end
to complete the circuit by having poor judgement/settings. They may be
able to write it to be better yet, though, and I'm hoping against hope, not.

Once again, the argument is not about what is on Tom's web page. The
argument is about what Tom asserted in his argument with Yuri on
eHam.net. Diverting attention to his web page is just, well, an
obvious diversion of the issue.

If I say there is no God on eHam.net and don't say it on my web page
does that prove I never said it?

You said:
> Since when has anyone claimed it's impossible to make a coil that
> has a non-constant current distribution?

When was August 10, 2003:

>>RE: In Search of 'The Perfect Mobile Antenna':
>>Reply by W8JI on August 10, 2003
>>Yuri, You are like to call names, insult people, and argue rather than
>>take the time to learn basic electronics. This is in any book, including
>>the ARRL Handbook. If you look at HOW an inductor works, the current
>>flowing in one terminal ALWAYS equals the current flowing out the other
>>terminal. THE VOLTAGE can be (and is) different on each end of the inductor,
>>NOT the current.

During that argument, W8JI presented the lumped inductance in EZNEC as proof
of the above statement.

I wouldn't be surprised to hear that it has been tried with rabbit
ears, but you would;
(1) have to adjust element lengths for each change of channel, and
(2) have to have lots of room on top of your TV set -- especially if the direction of
the
station is not ideal for your room!

On the higher channels it might not
be too bad! In addition, if you used a rotor you might end up gaussing up the screen
beyone the point of degaussing! :-)

The net (total) current on a standing-wave antenna is the phasor sum
of the forward current and reflected current and can change simply
because it is part of a standing wave. The change in net current at
the tip of a standing-wave antenna simply means that the energy has
moved from the H-field into the E-field.

What a lot of people are missing is that a relatively constant forward
current flows into the bottom of the coil and out the top. That current
is reflected from the tip of the antenna and a relatively constant
reflected current flows into the top of the coil and out the bottom.
The current at the bottom and top of the coil is the phasor sum of
those two currents and cannot help but be different for the typical
mobile bugcatcher antenna.

The net total current is the sum of those two currents and even if the
component currents are constant, their phasor sum will differ because
the phase of the component currents are changing in opposite directions
across the bugcatcher coil.

The cosine current distribution on a standing-wave antenna is just a
standing wave caused by the superposition of forward and reflected
current.

For a vanishingly small inductor, the phase shift through the inductor
is near zero and indeed results in the same current on both sides of
the inductor so the theory works just fine.

I purchased a PRO-2026 Radio Shack 100 channel scanner, this came with an antenna "WINDOW MOUNT"
Now with this WINDOW MOUNT ANTENNA - through scanning, 1 only receive 5 or so staions, rest are mostly static.
Do I need to replace this antenna - or - is there a way of tuning this ?,,,,,
Or should I replace this with a different one... if so can someone reccomend one ?
THANX

plug your TV antenna in the back, if it makes a huge difference and you start to hear more, your best getting a better/higher antenna.
Little telescopic antenna or window/ mag mount, are good for close car to car comms or powerful broadcasts, but scanning is different. For the best reception you need an antenna tuned for every separate frequency and there are lots of frequencies on a scanner (impractical)
Get a ham antenna book it will show you how to build your own antenna, out of bits of wire lolly sticks and tape, at a fraction of the cost.

Cecil,

You are using fightin' words, but I will play along. (I said "modified", not "wrong".)

I followed the URL quoted on Yuri's web site,

http://www.eham.net/articles/5998

It appears to me that W8JI made his first comment on this topic on August 7, 2003. The "ALWAYS" exchange with Yuri took place on August 10.

Over the next week there were numerous messages. W8JI explained how there could be a current change if the coil exhibited capacitive coupling, yada, yada, yada.

On August 17 W8JI posted a summary which clearly outlined his position. This is essentially the same position that has been detailed on his web site.

I don't care one way or the other about just how the personality battle started. You may see it differently than I do. However, it seems pretty clear, with the exception of one hyperbolic "always" comment, W8JI fully understands that the current can be different at the ends of a real-world coil.

I am not going to engage in a semantics battle with you or anyone else. If you don't agree with my interpretation that's fine with me.

Wes, N7WS wrote:
"Could you describe in more detail what the "pictures" are saying."

My edition of "Low-Band DXing" is copyrighted in 1994.

The "pictures" are graphs of current distribution on (6) different
1/4-wave vertical antennas:
1) full size
2) base loaded 1/8-wave of wire
3) capacitive hat loaded 1/8-wave
4) center loaded 1/16-wave wire above & below
5) continuously loaded (all coil) antenna
6) combined top and base loading of short vertical

The current distribution graphs are in a section (2.1) titled
"Radiation Resistance"

In every case , the current tapers lower from feedpoint end to the
loading coil`s end nearer the open end of the antenna. Devoldere
discusses the various loading methods.

Devoldere says the full size 1/4-wave vertical has a radiation
resistance of 36.6 ohms. His 50% length base loaded example has a
radiation resistance of 6.28 ohms. His top loaded example has a
radiation resistance of 18.3 ohms. His center loaded example has a
radiation resistance of 22.1 ohms

Radiation resistance is our goal. Radiation resistance versus total
resistance (radiation+loss resistances) is the antenna efficiency.

The all coil antenna has a calculated radiation resistance of 16.4 ohms.

The point is that all loading coils show less current at the top than at
the bottom because that`s the way it is, superposition.

Now that we`ve been re-Bushed, I`ve had time to answer Wes` question.

Best regards, Richard Harrison, KB5WZI

Source record: 87091

Cecil,

I cannot speak directly for Tom Donaly, but you and I are about 99% in DISagreement over physics.

One more time:

Current, charge, voltage, E-field, and H-field are different physical entities. They are related, but they are not interchangeable.

No amount of E-field, H-field, or voltage can create or destroy charge. Current is the movement of charge. At any point in space that charge must either keep moving (Kirchhoff's current law) or it must be stored (continuity equation). There is absolutely no other choice, period.

Your traveling wave/standing wave model is intuitive, but otherwise useless. Many authors reference such a model, but no one seems to use it for serious calculations.

You have started quoting Balanis:

"The current and voltage distributions on open-ended wire antennas are similar to the standing wave patterns on open-ended transmission lines ... Standing wave antennas, such as the dipole, can be analyzed as traveling wave antennas with waves propagating in opposite directions (forward and backward) and represented by traveling wave currents If and Ib ..."
_Antenna_Theory_, Balanis, Second Edition, Chapter 10, page 488 & 489

I do not have easy access to the Balanis book at this time. Does he go on to actually perform antenna calculations such as actual current distributions and radiated fields? I found the table of contents for this edition of his book, and it appears that Chapter 10 is a chapter on traveling wave antennas, not basic dipoles. If so, then it is likely that Balanis is merely trying to tie the entire world of antennas together to give a warm and fuzzy feeling to the reader.

Every detailed professional treatment of antenna theory and modeling I have found starts with Maxwell's equations, and quickly gets immersed in integral equations, Green's functions, and other messy stuff. Why would people do this if the mere application of a couple of traveling waves would provide the correct answers?

Do you have a reference to an analytic treatment using the traveling wave model that could give results comparable to NEC2? If so, I would sure like to find that reference.

73,
Gene

Point is, W8JI has never retracted his false statement.

What he has missed is that all those effects he lists affect both the
forward and reflected currents on a standing-wave antenna. The major
effect in the change in NET current is simply the superposition of
the forward and reflected waves with their differing phases from end
to end in the antenna.

As usual, Cecil is very selective of his quotes. Balanis uses a
highly mathematical approach in most of his book, supplemented by
many graphs and charts. Cecil's quote, like his quote of Tom Rauch
on loading coils is only a very small part of the total.

Pascuale,

I had a TA33JR a few years ago. When I installed a 20 meter dipole as a test some years later, I found the dipole had more gain than the 33JR on paths over about 2000 KM. The dipole was about 2 - 3 meters higher. From W2 to eastern Europe, the difference was consistently over an S unit. From W2 to Florida they were about even, but the direction of the dipole was not optimum. I now have a Hygain TH3.

Ruben Undheim wrote:
"Should I use the water pipe system as a ground, or should I use a thick wire dowen to a ground rod?"

A 20M dipole needs no RF ground. It may get a lightning surge in search of ground, a path to the earth.

To dissipate the surge to earth it is advantageous to use the same path as the radio power supply takes to earth, not to create a big potential difference within the radio.

As the power service to the radio may have a high RF impedance, which would also oppose a surge, it is a good idea to also connect the thick wire down to a ground rod.

Arc-gaps between the antenna feeders and the radio case may encourage a surge to take the direct path to earth. The radio case must also be connected to the electrical ground and the new ground rod at this point (perhaps your shack).

All earth grounds must be connected together using approved connectors to satisfy most electrical codes and to avoid differences of potential between earth connections. Voltages and currents can be so large that solder can melt. Welding or specified connectors are required.

If lightning takes the direct route to the earth via the arc-gaps, there will be less stress on the electrical system.

Best regards, Richard Harrison, KB5WZI

Gene, W4SZ wrote:
"Do you have a reference to an analytic treatment using the traveling wave model that could give results comparable to NEC2?"

NEC2 must agree with reality else it is worthless.

Terman agrees with Balanis and is only wrong when theory is revoked.
Terman says on page 866 of his 1955 edition:
"A wire antenna is a circuit with distributed constants; hence the current distribution in a wire antenna that results from the application of a localized voltage follows the principles discussed in Chap. 4, and depends upon the antenna length, measured in wavelengths; the terminations at the ends of the antenna wire; and the losses in the system. The current distribution is also affected by the ratio of wire length to diameter in situations where the antenna is unusually thick. (see Kraus, Schelknoff, and Friis) Under most circumstances, the losses are sufficiently low and the ratio of wire length to diameter sufficiently great so that to a first approximation the current distribution can be taken as that for a line with zero losses; it then has the characteristics discussed in Sec. 4-5."

Sec. 4-5 is titled: "The Effect of Attenuation on Voltage and Current Distribution - Lossless Lines" This is in Chapter 4, "Transmission Lines".

Best regards, Richard Harrison, KB5WZI

Mike, a receiver that does not provide for external antenna connection, will probably not benefit from forcing the input of one. The front end design of many portables uses double-conversion only, this allows for reception of fairly weak signals from the provided whip antenna. But it does not always bode well when powerful inputs such as an external antenna can provide, overloading the little portables and making it more difficult to discern between stations close to each other. Recommend you use your portable for what it was intended for, and look into adding a tabletop receiver if you want to input external antenna feed.

>radiation resistance of 18.3 ohms. His center loaded example has a
>radiation resistance of 22.1 ohms

Hi Richard,

This material has all the hallmarks of pencil whipping. The radiation resistance of an antenna is NOT necessarily the same as its drivepoint impedance at resonance. Without expressing the size of the radiator in each of the examples above, I am forced to consider that the reason for such loading examples is that the structure is significantly smaller than a quarterwave. I say this principally due to the inference of one line:
> His 50% length base loaded example
If we are speaking of a 1/8th wave tall radiator under different loading conditions, then it follows that the "radiation resistance" is incorrectly applied to drivepoint Z with a forced resonance due to loading.

Similar pencil whipping occurs when discussion centers on folded antennas that purport to raise "radiation resistance" when in fact they are simply raising drive Z. The argument in that vein generally plods on that even so, efficiency is raised. Then the argument is dashed in that the loss resistance is ALSO raised by the same mechanism and the efficiency either suffers by comparison, or at best breaks even.

This is the bane of loading, it introduces new sources of loss in comparison to the native "radiation resistance" that is unaltered by their inclusion.

> DISagreement over physics.

That's just a straw man, Gene. You school and my school probably taught 99% the same physics. You and I are not that far apart at all. THERE ARE NO CONTRADICTIONS BETWEEN THE PHYSICS YOU USE AND THE CONCEPTS I AM PRESENTING. It only appears that way to you because you haven't taken the time to understand those concepts.

Are there standing waves on a standing wave antenna? Are standing waves caused by the superposition of forward and reflected waves? Absolutely nothing new or different there.

> Current, charge, voltage, E-field, and H-field are different physical
> entities. They are related, but they are not interchangeable.

Straw man alert! I resent any implication that I said they were interchangeable. I agree with you about the above quantities.

> No amount of E-field, H-field, or voltage can create or destroy charge.

Straw man alert! I resent any implication that I said charge could be destroyed. I agree with what you said about charge.

> Current is the movement of charge. At any point in space that charge
> must either keep moving (Kirchhoff's current law) or it must be stored
> (continuity equation). There is absolutely no other choice, period.

EXACTLY! And that is exactly what you and W8JI are missing. The familiar cosine current distribution on a dipole is a standing wave, i.e. the net current in that standing wave is not moving. Therefore, the net current doesn't obey your rules above. The net current is just an artifact of superposition of the forward current wave with the reflected current wave. It is the forward current and reflected current that is moving. Until you and Tom understand the nature of standing-wave antennas, you will never understand the nature of the current(s) through a loading coil installed in the middle of a standing wave antenna.

Kurt N. Sterba made the same mistake in this month's Worldradio article. In a standing-wave antenna, the net current doesn't flow and RF current cannot stand still. The current is zero at the tip of a standing wave antenna not because all the energy has been radiated and/or conducted away by displacement currents. The current is zero because all the energy at that point is contained in the E-field. The forward H-field and the reflected H-field cancel each other at the tip of a standing wave antenna. If you really think there is zero energy at the tip of

a mobile antenna, please grab it while power is applied.

> Your traveling wave/standing wave model is intuitive, but otherwise
> useless.

Until you take the time to conceptually understand standing wave antennas, there is absolutely no chance of you understanding what happens when a loading coil is inserted in a standing wave antenna.

> sure like to find that reference.

There are some problems that do not lend themselves very well to a quantitative analysis. That's why simulation modeling is so popular with antennas and Blackjack.

However, the difficulty of a quantitative analysis should not turn your brain into concrete such that you reject the associated qualitative analysis. All of these qualitative concepts are presented in textbooks. I have only quoted a handful of them.

Terman, Kraus, Balanis, ... what do they know? :-)

Apparently, a lot of the otherwise knowledgeable people on this newsgroup have forgotten that the formula for the characteristic impedance of a single-wire transmission line is 138*log(4h/d) where h is the height of the wire above ground and d is the diameter of the wire. There's no difference between that single-wire transmission line and a lot of ham antennas. That single-wire transmission line radiates just like an antenna.

1/2WL of #16 wire 24 feet in the air has a Z0 of 600 ohms.

If that center-fed dipole were terminated at each end with a 600 ohm load, it would be a traveling-wave antenna with a feedpoint impedance of 600 ohms. Take away the loads and there's a match to 50 ohm coax at the feedpoint.

The only difference in those two antennas is that removing the loads turned the antenna into a standing-wave antenna and reflections are arriving back at the feedpoint, lowering the feedpoint impedance.

Any coil installed in a standing wave antenna is going to be subjected to both forward and reflected currents. There is no hope of understanding the current in a loading coil without understanding the component currents flowing both directions through the loading coil.

Richard Cl;ark wrote:
"The radiation resistance of an antenna is NOT necessarily the same as the drivepoint impedance of the antenna."

True, but for many resonant antennas they are identical.

Fundamentally, the radiation resistance is the value when inserted in series with an antenna will consume the same power as that radiated. Unless otherwise specified, the radiation resistance is referred to a current maximum point in an ungrounded antenna, and to the base of a grounded antenna. See 1955 Terman page 890 and 1950 Kraus page 143. They agree.

All of ON4UN`s loaded antennas have maximum current at their drivepoints and they are resonant, so their feedpoint resistance coincides with their radiation resistance in all the instances diagrammed in the current distribution chart for short loaded verticals. ON4UN starts with 1A current to the base of all antennas and the current declines from that value. Its value is the cosine of the number of degrees from the feedpoint in most cases.

That's simply a false statement and your agenda seems to
be personal rather than technical. Whose sacred cow am
I goring?

I say there are standing waves on a standing wave antenna.
You disagree "completely" with everything I say. So, Gene,
please prove that standing waves are absent on a standing
wave antenna. After that, please explain why they are
called "standing wave" antennas. Also explain why you
think Terman, Kraus, and Balanis are wrong in their
explanations of how standing waves exist on standing
wave antennas.

Hi Richard,

My point is that this does not follow. The drivepoint Z is NOT the "radiation resistance" irrespective of loading transformation. You can build a very small radiator, load it to resonance and it offers extremely poor efficiency. Examples abound.

Arguing about the "true" meaning of radiation resistance is pointless. If you'll look through various respected texts and references, you'll see that it's used by different authors in different ways. (I posted some specific examples quite a long time ago on this newsgroup -- I'll find and repost if anyone is interested.) Some authors refer it to a current loop; others use it to describe the feedpoint resistance, at resonance or not. In "folded" antennas, it can mean either the "unfolded" resistance or the transformed feedpoint resistance. The only common thread in usage is that it always represents a sink for the power which is radiated, so this is the only "true" meaning of the term. The greatest danger in being careless about usage is in blindly using some formula such as a common one for efficiency, Efficiency = Rr / (Rr + Rl). This works only if Rr and Rl are referred to the same point. For example, if used for a folded dipole or unipole, both Rr and Rl must be as measured at the feedpoint, where they're both transformed by the "folding" process; or both defined as properties of the unfolded antenna. Using the "folded" value of one and "unfolded" value of the other leads to incorrect conclusions about efficiency -- conclusions which been successfully used to sell antennas.

A given antenna doesn't have a single "inherent" or "fundamental" value of radiation resistance -- it's different at every point along an antenna, and the term can be legitimately used to describe the radiation "loss" component at any point. So whenever there's a chance of misunderstanding, it's important to say exactly what you mean by "radiation resistance" -- that is, where on the antenna this equivalent resistance is -- whenever you use the term.

I live in an antenna restricted area but have a large grounded aluminum pool cage that I am thinking about trying to use as an antenna. It is about 30 ft by 30 ft and 20 feet high. I checked with an ohmeter and all the aluminum support members appear to be well connected to each other.

Not wanting to reinvent the wheel , has anyone attempted to do this? If so how did you go about feeding it?

I had been thinking about a shunt feed arrangement for 30 or 40 meters as a starting point.

Any ideas?

Forgotten? How can we forget a "fact" we learned wasn't true in the first place?

According to the many references I have, the equation you quote is a simplified equation that's valid for a single wire over a perfect conducting ground plane, where the height is a very small fraction of a wavelength (i.e., radiation is negligible). Even when you ignore the relatively poor conductivity and the permittivity of real ground, the equation is certainly not valid if the wire is high enough for significant radiation to take place. There are several reasons for this:

1. The field shapes become different from the shapes assumed in deriving the equation.
2. Radiation would make the impedance complex rather than purely real.
3. The voltage between the conductor and ground depends on the path taken to measure it, so "characteristic impedance" takes on a whole different meaning, if it has any at all in this context.

There is, of course, also the problem of ignoring the finite conductivity of real ground, which will likewise impact the angle of the impedance.

It's surely tempting to take a nice, simplistic equation like this and build from it a whole theory of how things work. The seductive thing about it is that it seems to work, sort of, for some special applications. But it's a house of cards, and is at its root based on invalid assumptions. So all the wonderful theories that follow from it are fatally flawed and not to be trusted.

As apparently the only person on this newsgroup to have "learned" this "fact", it would serve you well to un-learn it. That is, if you're really interested in discovering how things really work rather than clinging to possibly mistaken notions about how they do.

Radiation Resistance.

Roy, what an excellent, well needed exposition, in plain English, addressed mainly to professionals who should know better, and are guilty (dare I say it) of obtaining money under false pretences.

You omitted only "DISTRIBUTED radiation resistance", a term essential to but absent from this newsgroup. It's probably also absent from Terman and Kraus, the latter I have never read. It's an aid to clear logical thought.

It should be used whenever radiation resistance is compared with conductor resistance, inductance, capacitance, etc., of elongated wires and loading coils.

As an example, it so happens that the distributed, end-to-end, radiation resistance, Rd, of a half-wave diopole is exactly twice (easily proved) the feedpoint resistance of around 72 ohms.

The radiating efficiency of a half-wave dipole is then, very simply and accurately -

Efficiency = 144 / ( 144 + overall HF conductor resistance )

although some old-wives may wish to argue about it on the grounds that it's far too simple.

|
|Hi Richard,
|
|This material has all the hallmarks of pencil whipping. The radiation
|resistance of an antenna is NOT necessarily the same as its drivepoint
|impedance at resonance.

True.

|Without expressing the size of the radiator
|in each of the examples above, I am forced to consider that the reason
|for such loading examples is that the structure is significantly
|smaller than a quarterwave. I say this principally due to the
|inference of one line:
|> His 50% length base loaded example

True.

|If we are speaking of a 1/8th wave tall radiator under different
|loading conditions, then it follows that the "radiation resistance" is
|incorrectly applied to drivepoint Z with a forced resonance due to
|loading.

I don't believe that Devoldere incorrectly infers this.
|
|Similar pencil whipping occurs when discussion centers on folded
|antennas that purport to raise "radiation resistance" when in fact
|they are simply raising drive Z. The argument in that vein generally
|plods on that even so, efficiency is raised. Then the argument is
|dashed in that the loss resistance is ALSO raised by the same
|mechanism and the efficiency either suffers by comparison, or at best
|breaks even.

Devoldere definitely debunks this idea.
|

|This is the bane of loading, it introduces new sources of loss in
|comparison to the native "radiation resistance" that is unaltered by
|their inclusion.

Loading with finite Q inductors surely introduces additional loss.
Nevertheless, the "real" radiation resistance can be increased beyond
that of the unloaded antenna. Hansen reports this in a paper
available at:

http://users.triconet.org/wesandlinda/HansenPaper.pdf

Or, model a short lossless monopole over perfect ground and determine
the feedpoint R. In this case, R is totally due to radiation loss,
i.e. "radiation resistance." Add a lossless loading inductance
somewhere in the middle and see what happens to R.

Regards,

Wes

Sorry, I take issue with this. The radiation resistance, as universally used in the professional literature, *is* a distributed radiation resistance -- it's the resistance that "consumes" the power radiated from the entire antenna, not just one point on the antenna. But that entire power-consuming property is commonly lumped into a single component -- the "radiation resistance" which can be defined (or "referred to") anywhere on the antenna you'd like, including but not limited to the feedpoint. And when placed at that point, it consumes the amount of power radiated from the entire antenna. It's not one single, absolute value, but a component whose value depends on where you define it on the antenna. A very simple and correct way of looking at it is to realize that if P watts is being radiated from the antenna, the radiation resistance value has to equal P/I^2, where I is the magnitude of the current at the point where you're measuring or defining the radiation resistance. So the radiation resistance always "consumes" P watts.

If you want to calculate efficiency, you have to do the same thing with the loss resistance, and make a single R that consumes the same amount of power as the total antenna loss. Again, you can define it anywhere on the antenna including the feedpoint, and it'll have a different value wherever you put it. To calculate efficiency from radiation and loss resistances, both have to be -- correctly -- defined at (or "referred to") the same point.

There's no need for additional "essential" fundamental terms -- the simple concept of radiation resistance as I've described it is perfectly adequate to explain and calculate antenna radiation and efficiency. But like other concepts, it does take a little effort to understand it.

Hi Wes,

The difference between the two (perfect/real) insofar as Z is hardly
remarkable.

First I will start with a conventionally sized quarterwave and by
iteration approach the short antenna and observe effects. I am using
the model VERT1.EZ that is in the EZNEC distribution and modifying it
by turns. For instance, I immediately turn on the wire loss.

40mm thick radiator 10.3 meters tall:
Impedance = 36.68 + J 2.999 ohms
which lends every appearance to expectation of Rr that could be
expected from a lossless perfect grounded world.
Best gain is
-0.03dBi

next iteration:

cut that sucker in half:
Impedance = 6.867 - J 301 ohms
which, again, conforms to most authorities on the basis of Rr.
best gain
0.16dBi
How about that! More gain than for the quarterwave (but hardly
remarkable). This makes me wonder why any futzing is required except
for the tender requirements of the SWR fearing transmitter (which, by
the way, could be as easily taken care of with a tuner).

next iteration:

load that sucker for grins and giggles:
load = 605 Ohms Xl up 55%
Impedance = 13.43 + J 0.1587 ohms
Did I double Rr? (Only my hairdresser knows.)
best gain
0.13dBi
Hmm, losing ground for our effort, it makes a pretty picture of
current distribution that conforms to all the descriptions here (sans

the balderdash of curve fitting to a sine wave). I am sure someone will rescue this situation from my ineptitude by a better load placement, so I will leave that unfinished work to the adept practitioners.

next iteration:

cut that sucker down half again (and remove the load):
Impedance = 1.59 - J 624.6 ohms
Something tells me that this isn't off the scale of the perfect comparison.
best gain:
0.25dBi
Hmm, the trend seems to go counter to intuition.

next iteration:

-sigh- what charms could loading bring us?
load = 1220 Ohms Xl up 55%
Impedance = 3.791 + J 1.232 ohms
more than doubled the Rr?
best gain:
0.23dBi

Now, all of this is for a source that is a constant current generator; we've monkeyed with the current distribution and put more resistance (Rr?) into the equation with loading; and each time loading craps in the punch bowl.

So much for theories of Rr being modified by loading. I would appreciate other effort in kind to correct any oversights I've made (not just the usual palaver of tedious "explanations" - especially those sophmoric studies of current-in/current-out).

I am interested on the effect of a HANE (High Altitude Nuclear Explosion) ionization effect (not EMP)on UHF to SATCOM frequencies up to 300GHZ. There was a naval experiment called Project Argus back in the late 50's investigating the effect of a HANE on radio communication and radar. Of course, back then no one was using UHF and SATCOM.

Except from a document dating back from the 80's dealing with MX-1 C3 which was very vague, there is not much data on this phenomena.

Even if everything you say is true, it doesn't nullify the concepts of physics. Even if the Z0 is changing point to point along the length of the wire, as it surely does for a vertical antenna, the idea that standing wave antennas don't possess standing waves is ridiculous.

The idea that the net antenna current on a standing wave antenna is not itself a standing wave is ridiculous. The idea that the net antenna current on a standing wave is not the result of the superposition of the forward current and reflected current is ridiculous. The idea that RF waves can stand still is ridiculous. The idea that current flows in only one direction in a standing wave antenna is ridiculous.

A Rhombic, for instance, is a traveling wave antenna. Its feedpoint impedance is equivalent to its characteristic impedance which is hundreds of ohms. In a standing wave antenna, it is the reflected wave superposing with the forward wave at the feedpoint that determines the feedpoint impedance, low for 1/2WL center-fed dipoles and high for 1WL center-fed dipoles. The feedpoint impedance depends upon interference between the forward wave and the reflected wave.

All you have proven is that this is a difficult subject to quantitize, but we already knew that. It is not a difficult subject to conceptualize.

So, Roy, please answer the following true/false questions.

Standing wave antennas actually exhibit standing waves as described by Kraus, Balanis, and others. ______

Standing waves are created by the superposition of forward waves and reflected waves. ________

RF waves cannot stand still. _______ If true, it follows that "standing" waves are an artifact of superposition and cannot exist without the two underlying component waves.

What is moving at the speed of light is the forward wave and the reflected wave. ________ Hint: RF waves must move at the speed of light. Therefore, RF standing waves have two components, each moving at the speed of light in opposite directions.

For what it's worth, here's a quote from The ARRL Antenna Book, 15th edition, page 24-22 under "Single Wire Line": "The characteristic impedance of the single wire line depends on the conductor size and the height of the wire above ground, ranging from 500 to 600 ohms for #12 or #14 conductors at heights of 10 to 30 ft." Nothing said about "perfect ground" or "small fractions of wavelength".

Again, the concepts that I discuss fall out perfectly from the laws of physics. That they are difficult to quantify is not a good reason to adopt a closed mind. (This reminds me of my Southern Baptist upbringing where some subjects were forbidden).

Real CATV amps cost too much to consider for the average single
home.

CATV co's usually spec the max outlets per outside drop to 4. It's
better to have another drop after that.

Off the shelf boosters... I'd like to see a cheap one that handles 1
GHz *and* passes the return channels.

# 1835. New Version of SmartSmith Program Available (Ver 1.4, Nov 5, 2004)

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-05 13:21:58 UTC
From: w9dmk@crosslink.net
Message-ID: <418b7e0a.2106158@news.crosslink.net>
Source record: 87030

An update to the "SmartSmith" program is now available at my Web Site
- http://www.qsl.net/w9dmk.

This new version (version 1.4, Nov 5,2004) incorporates several new
features, as follows:
Modeling of Matched Line losses in transmission lines and stubs,
including the additional loss due to SWR.
Additional Tutorials in the Help file, including design of Pi matching
sections.
Data logging to the disk, allowing you to keep a record of the design
steps.

The new version can also be downloaded directly from this link:
http://www.qsl.net/w9dmk/SWDownloads/SmartSmith14.zip

Tnx a lot Tam.
First of all, sorry for my bad english.
I have a little space for my antennas so I'm looking for a little triband 10,15 and 20 meters. I'm interested to Mosley product, expecially TA33-JR or TA32-JR. I read on eham.net (www.eham.net) any reviews about these antennas and everybody are enthusiastic.
I'm interested also to HyGain TH3JR but weights is a little more than Mosley's.
Any news or ideas is appreciated.

Roy Lewallen, W7EL wrote:
"Sorry. I take issue with this. The radiation resistance as universally used in the professional literature "is" a distributed radiation resistance---."

One definition, but not universal by any means.

Terman is as professional as needed for most purposes. Terman defines radiation resistance and the custom for stating it on page 891 of his 1955 edition:
"Unless specifically stated to the contrary, it is customary to refer the radiation resistance to a current maximum in the case of an ungrounded antenna, and to the current at the base of the antenna when the antenna is grounded."

Terman`s definition is unequivocal and useful. It is echoed by other authors.

Kraus says on page 182 of his final 3rd edition:

"Ro = 60 times the intergral, zero to pi, of the square of Cos [(beta L/2) cos theta] - cos(beta L/2) / sin theta, d theta

Where the radiation resistance Ro is referred to the current maximum.

In this case of a 1/2-wave antenna, this is at the center of the antenna or at the terminals of the transmission line (see Fig. 6-7)."

The solution for a thin dipole yields 73 ohms.

Of course, the impedance of a standing-wave antenna varies continuously along its length due to interaction of waves traveling in opposite directions. For practical purposes, we can define Ro as the resistive part and transform its value to the antenna input terminals if these don`t correspond to a current maximum.

Best regards, Richard Harrison, KB5WZI

My guess is that the 2 element full power beam like the TA32 or TH2 will outperform the 3 element juniors. The traps on these 3 element beams are very small, and the element spacing too close. The 2 element will have a slightly shorter boom, but slightly longer elements. Also, the junior beams will not withstand much power. I burned out a trap on the TA33JR by operating with a linear amplifier. The directivity and F/B ratio on the TA33JR were very poor.

I had the TA33JR for 20 years, and did not start to question its performance until I started doing comparisons.

Heh, heh, since you don't know the last digit of pi, Roy
probably won't allow you to use it. :-)

> Where the radiation resistance Ro is referred to the current maximum.

The point seems to be that the impedance at the current maximum
point includes terms besides radiation resistance. In simplified
form, for a resonant antenna, Rfeed = Rrad + Rloss

Rloss includes I^2*R losses and ground losses and is sometimes
negligible and sometimes not.

For some antenna configurations, Rloss is negligible, so the
feedpoint resistance can be very close to the radiation
resistance, e.g. a dipole in free space.

For other antenna configurations, Rloss is much greater than
the radiation resistance, e.g. an 8 foot center-loaded 75m
mobile antenna.

My screwdriver has approximately a 12.5 ohm feedpoint resistance
on 75m. I consider approximately 10 ohms of that to be ground
loss.

Thanks for that Jack, I see your point. The receiver in question is a
Sony XDR-S1 DAB and I'm in a marginal reception area. Before I spent
out on DAB I tried one (not the Sony) and the reception was
reasonable, the Sony isn't as good though and I just thought that
maybe I could help it a bit with an external aerial.

Thanks for your thoughts,

Mike

Richard,

It is not clear just what you were trying to demonstrate, but there was no obvious connection to Rr. Maximum gain is unrelated to Rr.

Were you looking for validation that you correctly loaded the numbers into EZNEC?

Looked OK to me.

(OK, so my trolling is not as professional as yours, but I tried.)

If you really are concerned about Rr, then consider the following.

Rr is defined by the equation:

Total power radiated = a*I*I*Rr,

where I and Rr are referred to the same point on the antenna.

For short antennas this reference point is generally taken as the feedpoint, which is also the current maximum point. There is no loss, so all power into the antenna is radiated. Therefore the Rr for each of your perfect world, zero loss examples is proportional to the feedpoint resistance. Apply an appropriate scaling factor (a) if you want the correct numbers.

Did you have a question about something?

The bottom line, of course, is that none of this matters in a perfect world with zero loss. All the power input is shot into space. Please let us know where we can find that perfect world :-)

73,
Gene

# 1855. Loop antenna electrostatic shields

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-05 19:35:00 UTC
From: Joel Kolstad <JKolstad71HatesSpam@Yahoo.Com>
Message-ID: <XqednfBGoctGSBbcRVn-iw@comcast.com>
Source record: 87050

When you build a loop antenna, it's common to wrap it in, e.g., aluminum foil that's grounded so as to prevent electric field pick-up (I'm thinking of HF loops here, <30MHz). A slit is made in the wrapping so that a shorted turn isn't created, thereby nulling out the magnetic field that the loop is trying to detect in the first place.

Something I don't understand, though... normally, if you were thinking of using aluminum for EMI shielding purposes, the skin depth of aluminum at 10MHz is all of ~1mil. Hence, a regular sheet of aluminum foil would significantly attenuate both the magnetic and electric fields on its 'far' side. Why doesn't this apply in the case of a shielded loop antenna? It seems to me that the ~95+% 'coverage' of the shield (everything minus the slit to prevent the shorted turn) would be what dictates the overall shielding effectiveness, not the presence of the slit itself.

Looking for insight,
---Joel Kolstad

Hi Gene,

The tenor of correspondence here would suggest otherwise. The
evidence of testing would suggest there is. The disconnect is that
the evidence counters the suggestions in correspondence.

>Were you looking for validation that you correctly loaded the numbers

>resistance. Apply an appropriate scaling factor (a) if you want the
>correct numbers.

Wholly unnecessary, EZNEC can cope with loss quite well and
demonstrates a real world solution (barring my errors of commission or
omission) within tolerable limits.

>Did you have a question about something?

>>I would appreciate other effort in kind to correct any oversights
>>I've made

Hi Jim,

I would have thought someone else could, given the bandwidth of
discussion in making the current taper shorter and the constant
current section longer. Testing does not bear their facile
relationship out however, and for the topic of a short antenna
(otherwise, why are we talking about loading coils?) it would seem
that antenna gain is immutable over several octaves below a
quarterwave length.

Of course, I coulda done something wrong. I did use a commonly
available design. I did use a commonly available modeler. I even may
have done the wrong thing in choosing a design that could be evaluated
for free. Perhaps I erred in providing the cogent details of
construction. It took all of 20 minutes to accomplish (far less time
than that expended in theories of current-in/current-out). These
technical hurdles appear to have set the bar too high for my work's
refutation in kind. I appreciate that "it's hard work!" ;-)

To answer your question, if you just abandon the perfect load, then
you stand to achieve a higher gain. If you shorten the antenna, then
you stand to achieve a higher gain. There is no change in Rr with the
addition of Xl. Hence the mathematical relationship for an antenna
shorter than quarterwave would be suggested as:
gain ~ 1/Rr
gain ~ 1/Xl
Rr <> Z

Don't take this gain to the bank however.

Apparently, you are not reading the quotes: From "Antennas For All Applications", by Kraus and Marhefka, 3rd edition:

From page 187 regarding standing wave ANTENNAS:
"A sinusoidal current distribution may be regarded as the standing wave produced by two uniform (unattenuated) traveling waves of equal amplitude moving in opposite directions along the antenna."

From page 465 regarding a dipole ANTENNA longer than 1/2WL:
"When the antenna (dipole) is infinitesimally thin, the phase varies as a step function, being constant over 1/2WL and changing by 180 deg. at the end of the 1/2WL interval. This type of phase variation is observed in a PURE STANDING WAVE." emphasis mine.

**********

From _Antenna_Theory_, Balanis, Second Edition, Chapter 10, page 488 & 489
"The current and voltage distributions on open-ended wire antennas are similar to the standing wave patterns on open-ended transmission lines ... Standing wave antennas, such as the dipole, can be analyzed as traveling wave antennas with waves propagating in opposite directions (forward and backward) and represented by traveling wave currents If and Ib ..."

I got my ideas from Kraus and Balanis, and in particular from Balanis' antenna courses at ASU where he found no fault with my ideas.

Do you agree or disagree with Kraus and Balanis that standing wave antennas exhibit standing waves? If they do, they follow the well known laws of physics governing standing waves.

The combined effort to suppers the ideas of Kraus and Balanis is getting more ridiculous with each passing day. It can no longer be explained by ignorance.

This is indeed an interesting result, even though it's small. As a dipole or monopole gets shorter than a resonant length, the current distribution changes from sinusoidal to triangular. In the ideal case (and in the absence of loss), this results in the shorter antenna having a slightly fatter pattern and therefore slightly less gain. An infinitesimally short antenna has a gain of less than 0.5 below that of a resonant one, due to this (and again, in the absence of loss). So the trend you observed was backwards. The first two things I checked -- segmentation and wire loss -- proved to not be the reason. It appears to be the effect of the current distribution on the reflected wave from the ground. The radiation from each part of the antenna reflects from the ground, and the nature of the reflection depends on the angle at which it strikes the ground. Radiation from different parts of the antenna strike at different angles, and the shorter antenna has its current, therefore its radiation, apportioned differently. It's this difference that causes the slight backward trend in gain. I wouldn't put too much weight on it, however, both because of its being small, and that EZNEC and similar programs use a pretty simple ray-tracing method of calculating ground reflection rather than a more complex method which includes diffraction and other effects. You'll see the theoretical trend

if you change the ground type to Perfect, and likely a slightly
different trend if you change the ground constants.

This makes me wonder why any futzing is required except

> practitioners.

As I pointed out above, going from a sinusoidal to a triangular
distribution changes the gain less than 0.5 dB, so this change in
distribution changes the gain even less. And again, the interaction with
real ground reverses the trend. With Perfect ground, you'll see that
there's actually a 0.02 dB gain improvement with the new distribution.
This is, of course, insignificant, but it does show that things are
working as they should.

> Hmm, the trend seems to go counter to intuition.

That's because you didn't understand the reason for the trend in the
first place. What's happening now is that the gain reduction caused by
the changed distribution is no longer overwhelmed by the gain increase
caused by the interaction with real ground. Again, go to Perfect ground
and you'll see that the trend of less gain as the antenna shortens is
continuing as exepected.

>

And with Perfect ground, the gain is the same within 0.01 dB with and without the load -- the modified current distribution wasn't enough to make any significant difference in the pattern and hence the gain.

>
> So much for theories of Rr being modified by loading.

Everything you've done shows that Rr is modified by loading. Rr at the feedpoint is simply the resistance at the feedpoint. And it clearly changes when you insert the load. What makes you think that the Rr isn't changing?

I would
> appreciate other effort in kind to correct any oversights I've made
> (not just the usual palaver of tedious "explanations" - especially
> those sophmoric studies of current-in/current-out).

Perhaps you're expecting the gain to vary in the same way as Rr. But you see, gain will change with Rr only if the pattern shape stays the same. And each time you insert the load, the current distribution changes, which changes the shape of the pattern, which changes the gain. This is the gain change you're seeing as you change the antenna length and add loading. The main relationship between Rr and gain is the efficiency. The antennas you've modeled are so close to being 100% efficient that increasing Rr has no appreciable effect on gain. Check it yourself -- make the antenna 100% efficient by removing the wire loss and notice that there's no change in gain (maybe 0.01 dB with the full size antenna).

But now repeat your experiments with, say, a 10 ohm resistive load at the base to simulate ground system loss. And you'll see that the gain improves dramatically as your loading increases Rr (the feedpoint resistance). This is due to the improved efficiency you gain by increasing Rr.

Point being that antenna gain has spatial implications which Rr by
itself could not provide in the solutions.

One should conclude from your results (very nice work, by the way) that the modeler apparently doesn't figure Xl as contributing to the radiation resistance. But isn't that basically the crux of the argument here - whether or not that is in fact the case? If not, then we would have to conclude that loading coil has zero physical and electrical length, and that the impedance is constant from one end to the other. Obviously I could be wrong, but I think those are the assumptions made in your modeling software. On the other hand, if the impedance of the coil is not constant from one end to the other, and it in fact does have some real physical and/or electrical length, then I think the radiation resistance of the antenna would have to be effected by its presence in the circuit. That is, if indeed Ro is the integral of disributed r along the entire physical and/or electrical length of the antenna (credit for that formula going to an esteemed contributor to this newsgroup earlier today). Or perhaps more concisely put, if the loading coil itself contributes to the field radiating from the antenna, then it should likewise have a Rr associated with it. The converse would of course still be true.

Again, words. I would offer that Xl does not adjust Rr (insofar as it
does adjust drivepoint Z). Let me add - much (there are miniscule
differences).

As I say above, it is not a difference of ZERO it is a miniscule
difference (with a negative correlation). I will leave it to others
to recapture (or diminish) gain through helix building. I am
satisfied those returns will be equally diminutive.

>Obviously I could be wrong, but I think those are the assumptions made
>in your modeling software.

We both could be wrong. No one has yet to step up to the bar and
offer work in kind.

This returns us to matters of degree. By simple observation comparing
the standard full sized radiator to ANY of the iterations, it is

obvious that nothing significant can be said of the physicality of the load, much less its contribution. In other words, is there some magical coil or magical placement that would create a short super-radiator that exceeds the performance of the standard quarterwave? [no here can recognize a eh/cfa claim?]

Let's put a handicap on this. Is there some magic combination of coil/position that would even EQUAL the performance of the standard quarterwave?

It might be helpful to elaborate a bit more about radiation resistance.

Consider an antenna that has no loss. If we apply 100 watts, say, to this antenna, the radiation resistance "consumes" that 100 watts. That is to say, all 100 watts is radiated.

In the case of a resonant lossless quarter wave vertical, for example, the current at the base will be about 1.67 amps if 100 watts is being radiated. We can solve for Rr at the base from P = I^2 * Rr, where I is the base current, to get Rr = P / I^2, with the result that Rr is about 36 ohms. This is the radiation resistance referred to the base -- it "consumes" the 100 watts. (We could have calculated Rr at some other point along the antenna, where I is different, and gotten a different value. But P still has to equal I^2 * Rr, where I is the current at the point to which Rr is being referred.)

Now, what determines the current we get at the base, for a given applied power and radiator length? The answer is the current distribution -- that is, the way the current varies along the length of the conductor. (I'm only considering a simple single wire antenna here. When other conductors are involved, mutual coupling between conductors also plays a role.) Putting a loading coil at the bottom of the antenna doesn't change the current distribution, it only changes the feedpoint reactance. So it doesn't change the feedpoint current for a given power input, so the radiation resistance doesn't change. But if you put a loading coil part way up the antenna, the current distribution does change. This alters the base current for the same power input and therefore the radiation resistance changes. Remember that Rr = P / I^2, where Rr and I are measured at the same point (in this case the base feedpoint), so if I changes, Rr changes. Likewise, top loading alters the current distribution and consequently the radiation resistance. For people who would like to see this graphically, the demo version of EZNEC is adequate. Just look at the View Antenna display after running a pattern, source data, or current calculation, and you'll see how the current varies along the antenna. If you set a fixed power level in the Options menu (Power Level selection), you can also see, by clicking Src Dat, exactly how the current at the source changes as the current distribution does.

If you have a fixed amount of loss, say at the base of the antenna due to ground system loss, the amount of power dissipated in that loss as heat is Ploss = I^2 * Rloss, where I is the current flowing through that loss, in this case the current at the antenna base. So for a given amount of applied power, you minimize the power lost when you minimize the base current. This is exactly equivalent to saying you're raising

the radiation resistance referred to the base. That's why mobile antenna users consider higher radiation resistance a virtue -- it means lower feedpoint current for a given power input, and therefore less power lost in the necessarily imperfect ground system.

While the principles are all the same, wire loss has to be treated a bit differently because altering the current distribution changes the amount of wire loss (which is usually combined into a single loss resistance referred to the feedpoint, or the same point where the radiation resistance is referred). Also, changing the wire length alters the wire loss, as does the total current in the wire which increases as the wire is shortened for a given power input. All these can be dealt with analytically or with a modeling program, but it's easy to lose track of exactly what's happening when all these factors are present at the same time. Fortunately, wire loss is insignificant for the vast majority of typical amateur applications. With modeling, it's easy to determine when it is and isn't significant, simply by turning wire loss on and off and observing how much the results change.

Loading.

You wrote:

>So much for theories of Rr being modified by loading.

Being a simple-minded, non-liberally educated person, I took this to mean that you'd shown that Rr isn't modified by loading, disproving theories that Rr is modified by loading. (Otherwise, I figured, you would have said "So much for theories of Rr not being modified by loading.")

Did you mean instead that there are theories that Rr isn't modified by loading? If so, who on earth is proposing those theories? As a basic understanding of Rr shows, and as your modeling results also show, there's no basis for such a "theory". What's next, a "theory" that V = I/R?

I wouldn't have it any other way, Richard.

The examination of the underlying theory taking place in this discussion resolves in different ways. Any other 'work in kind' would depend largely on which way one resolves the theory. Horse first, then cart.

Reasonable questions have been posed here. Some of the points being raised remain to an extent, unreconciled with certain aspects of conventional treatments. Obviously, thanks in no small part to empirical methods, this poses no greater hinderance to the design of efficient antennas than does the lack of a precise understanding of the nature of turbulent flow to the design of efficient fluid pumps. I find any contention that no further investigation is necessary to be less than convincing. On the contrary, the work done by the oft cited E&M engineers clearly indicates there is more to the story - a point that said engineers would undoubtedly concede without hesitation.

Absent a thorough understanding of the phenomena, one might be inclined to conjecture about magical things. But I'm inclined toward taking satisfaction from persuing a thorough understanding of the phenomena rather than from strutting the pretense of already having one.

Concerning current distribution -- at least on a monopole above a perfectly conducting ground. I have noticed that in any antenna, of any length, inductively loaded, or not, the: Integral of I(z)dz (where the units of dz are in fractions of a wavelength, and I(z) the current distribution) is virtually a constant. Assuming the same input power in all cases. Suppose it seems pretty obvious since the total radiated power from any structure is also essentially constant. I must admit I have not seen gain increasing, with decreasing size, but then I have not seriously tried.

Regards,

Frank

|>i.e. "radiation resistance." Add a lossless loading inductance
|>somewhere in the middle and see what happens to R.
|
|Hi Wes,
|
|The difference between the two (perfect/real) insofar as Z is hardly
|remarkable.

True.
|
|First I will start with a conventionally sized quarterwave and by
|iteration approach the short antenna and observe effects. I am using
|the model VERT1.EZ that is in the EZNEC distribution and modifying it
|by turns. For instance, I immediately turn on the wire loss.
|
|40mm thick radiator 10.3 meters tall:
| Impedance = 36.68 + J 2.999 ohms
|which lends every appearance to expectation of Rr that could be
|expected from a lossless perfect grounded world.
|Best gain is
| -0.03dBi
|
|next iteration:
|
|cut that sucker in half:
| Impedance = 6.867 - J 301 ohms
|which, again, conforms to most authorities on the basis of Rr.
|best gain
| 0.16dBi
|How about that! More gain than for the quarterwave (but hardly
|remarkable). This makes me wonder why any futzing is required except
|for the tender requirements of the SWR fearing transmitter (which, by

|the way, could be as easily taken care of with a tuner).
|
|next iteration:
|
|load that sucker for grins and giggles:
| load = 605 Ohms Xl up 55%
| Impedance = 13.43 + J 0.1587 ohms
|Did I double Rr? (Only my hairdresser knows.)
|best gain
| 0.13dBi
|Hmm, losing ground for our effort, it makes a pretty picture of
|current distribution that conforms to all the descriptions here (sans
|the balderdash of curve fitting to a sine wave). I am sure someone
|will rescue this situation from my ineptitude by a better load
|placement, so I will leave that unfinished work to the adept
|practitioners.
|
|next iteration:
|
|cut that sucker down half again (and remove the load):
| Impedance = 1.59 - J 624.6 ohms
|Something tells me that this isn't off the scale of the perfect
|comparison.
|best gain:
| 0.25dBi
|Hmm, the trend seems to go counter to intuition.
|
|next iteration:
|
|-sigh- what charms could loading bring us?
| load = 1220 Ohms Xl up 55%
| Impedance = 3.791 + J 1.232 ohms
|more than doubled the Rr?
|best gain:
| 0.23dBi
|
|Now, all of this is for a source that is a constant current generator;
|we've monkeyed with the current distribution and put more resistance
|(Rr?) into the equation with loading; and each time loading craps in
|the punch bowl.
|
|So much for theories of Rr being modified by loading. I would
|appreciate other effort in kind to correct any oversights I've made
|(not just the usual palaver of tedious "explanations" - especially
|those sophmoric studies of current-in/current-out).

Sure. Your calculations are impeccable so far (although it would be
better to use more than 10 segments IMHO).

I believe it is your contention that loading to resonance with an
arbitrarily positioned inductor, or not loading at all, does not

affect the gain, and the radiation resistance is not the same as the changing feedpoint resistance.

I am in the other camp, along with Hansen, Devoldere, et. al. who say that the current distribution does affect the radiation resistance (and in the real world, the gain/efficiency).

I hope you would agree that the normalized gain would be a good proxy for efficiency.

For example if we use the lossless 1/4 wavelength monopole over perfect ground as a reference, then gain with respect to that (5.15 dBi) would be an indicator of efficiency.

I believe that you will agree that the efficiency can be determined by:

$$\text{eta} = \frac{Rr}{Rr + Rg + Rl} \quad \text{Eq.1}$$

where Rr = radiation resistance
Rg = ground resistance
Rl = all other resistances (conductor, etc)

I think you would also agree that for the full-sized monopole over perfect ground the feedpoint resistance of ~36 Ohm = radiation resistance.

As an old (sorry [g]) metrologist, you're very familiar with substitution, so let's set Rl = 0 (lossless case) and eta to 0.5 (-3 dB). Per Eq. 1, Rg = Rr.

So in our model, if I add a simulated ground resistance, Rg, that reduces the gain by 3 dB, I have by substitution, determined the radiation resistance.

Sure enough, if I add a 36 Ohm load at the bottom of the perfect 1/4 wave monopole, the gain drops to 2.14 dBi, and the feedpoint resistance doubles.

I will let you try this with the other cases. I trust you will find that the radiation resistance does decrease with shorter radiators and/or lower loading points.

I too I would appreciate other effort in kind to correct any oversights I've made.

Wes

Hi Frank,

What would you say to "assuming the same current in all cases" and
either/both the Rr and drivepoint Z have changed to no particular
evidence in the far field?

I have been posited with
>a "theory" that V = I/R?
to which I would wryly note that nothing has been said of V (and
certainly no interest has been shown), I is known and observations of
P (as evident in the far field, which has occurred to me may be the
issue - had to say it for myself, didn't I?) for a changing R
(somewhere through the iterations).

Ah, yes, that's one of those simple observations that lures people into making false generalizations. I think you'll find that your observation isn't true for any length, but only for lengths of a quarter wavelength (for a monopole) and shorter. And only for an antenna consisting of a single straight wire. Under those conditions, the phase of the current is nearly constant along the wire, so the fields from the various parts of the antenna add together in phase at a distant point broadside to the wire. The maximum field strength is, therefore, proportional to the sum of the fields from the individual segments which, in turn, is proportional to the integral of the currents on the segments. Since the maximum field strength (or gain) doesn't change much from a very short wire to a quarter wavelength one, the integral of the current stays pretty constant. But don't, for heaven's sake, think you've discovered a rule that applies for all antennas. Not even all straight, single wire monopoles.

Oh, I would never make such an assumption that it applies to all antennas -- well maybe it did cross my mind!. My guess was that probably everybody knew it anyway, but thought it was interesting. I have also noticed that the phase of the current is constant over thin wire monopoles of less than a 1/4 wave

Regarding Richard's comments "Assuming the same currents". Not sure I understand, since the feed-point current varies with constant power -- as does the voltage. Also confused by the expression V=I/R.

Hi Frank,

That is quite simple. The file VERT1.EZ has as a source, a constant
current generator - a fact I pointed out in the summary of my results.
Your presumption of constant power is a natural one for the sake of
common discussion, but it is not even the default source for EZNEC.

[However, having said that, a curiosity of program design has found
that the concept of a "new file" has been orphaned. Any time the
application is opened, it is opened with LAST.EZ and I cannot recall
upon initial acquisition if EZNEC ever started with a blank slate.
Given that you cannot have less than 1 wire nor 1 source, then there
is on way to force a blank file. Hence the concept of a default
resides in the last file opened.]

In other words, each and every iteration of antenna, irrespective of
its presumed or actual Rr or drivepoint Z had the same current applied
to it, 1 Ampere.

Now, if ANY resistance had changed, it then follows that the POWER
would have changed too (which presents us with that puzzle
>confused by the expression V=I/R.
that came out of the blue) at a linear rate (1ï¿½ = 1).

Note, a doubling of drivepoint Z by the addition of a load does not
result in 3dB gain over the former design. I have seen I * I * R
bandied about as an "explanation" and yet at least 3dB is remarkably
absent in the results. What R is this that everyone speaks of?
Certainly not the real component of drivepoint Z. What about the Rr
that must've changed? Copper loss absorb it? Ground loss?

As I offered, I must've done something wrong, taken the wrong turn,
interpreted the modeler in error, -ahem- not read the help file....

I will bet it was that last one - which only reveals no one has. ;-)

[aside]
So, Wes, I will amend my ways and delve into that treasure of
knowledge before returning your work in kind (no point in retread
effort) sometime tomorrow morning.

[to the audience]
C'mon folks, this has to be an especially simple resolution - I'm glad that so many are just as flummoxed (even Reg is uncharacteristically silent in this regard :-)

If you "google" search on Project Argus and James Van Allen's work related
to his earlier discovery ("inner"and "outer" radiation belts with Explorer I
and III) and work (Aurora work with Navy and rocketoons) .. there is some
commentary that may be of interest.

I'd be glad to help clarify any confusion, but I can't for the life of me figure out what the confusion is about.

Regarding EZNEC's sources, you have the option of using a constant-current source, constant-voltage source, or having a fixed power applied to the model. If a fixed power level is chosen, multiple sources will have the same ratio of voltages and currents as you've specified. For example, if your model has two sources, one of 1 amp and the other 2 amps, and you choose a fixed power level, the current from the second source will always be twice the current from the first (and at the specified relative phase), but both will be modified as necessary to produce the total power you specified.

Fixed power is selected in the Options menu. While the relative source currents (2 amps and 1 amp in the example) are saved with the model, the Options menu choices aren't. They're applied to all models. Changes you make in the Options menu remain effective until you end the program. If you choose "Save as Default" from the Options menu, the current settings will remain in effect even after you end the program, until you change them.

I don't personally use a fixed power level very often, since I'm more often interested in things like currents on wires relative to a source, so it's convenient for me to set the source to 1 amp. The fixed power level is useful whenever you need an absolute value of voltage or current, though, or want to see how the voltage, current, or load power dissipation changes as you modify the model. It can be helpful in understanding radiation resistance, by illustrating the relationship among feepoint power, current, and resistance.

Just what is it that's confusing about radiation resistance and EZNEC results? Richard's EZNEC results are exactly what I'd expect, and they're consistent with theory. (I'm talking about established theory found in textbooks, not ones cooked up by people who don't understand basic principles or common nomenclature.) The small gain change due to the ground reflection reaction to altered current distribution was admittedly a surprise, but it makes perfect sense after a moment's thought. If someone can summarize what seems to be wrong, I'll do my honest best to explain it. Is the problem that the gain doesn't go up with Rr? Of course it doesn't, in the nearly lossless antennas of Richard's models. Why should it? I tried to explain why in my earlier posting, but I'll try again if that's what the problem is.

|discusses the various loading methods.

Yes, but as I mentioned in my analysis at:

http://www.qsl.net/n7ws/Loaded%20antennas.htm

for the extremely short antennas that were (are) the subject of the "shootout" business, the current actually increases between the ends of the inductor.

John Smith wrote:
"Oh...This is about gain?"

Don`t think so. This is about unequal currents into and out of an antenna loading coil. The effect a loading coil has on received signals is due at least in part to its effect on radiation resistance versus total (radiation + loss) resistance. If you increase radiation resistance as comared with loss resistance you increase effective radiated power. Directive gain has nothing to do with loss.

Here is Terman`s comment on gain in Note 2 on page 870 of his 1955 edition:
"Directive gain depends entirely on the distribution in space of radiated power. The power input to the antenna, the antenna losses, or the power consumed in a terminating resistance have nothing to do with directive gain. Such factors are taken into account in terms of the power gain of the antenna which is defined as the ratio of the power input to the comparison antenna required to develop a particular field strength in the direction of maximum radiation, to the power input that must be delivered to the directional antenna to obtain the same field strength in the same direction. Unless otherwise specified the comparison antenna is a lossless isotropic radiator."

Best regards, Richard Harrison, KB5WZI

Actually, it just moves to a straighter portion of the sinusoidal
curve. The cosine curve from 75 degrees to 90 degrees does resemble
a triangle but it is not a straight line. Assuming a triangle from
75 deg to 90 deg is a simplified shortcut that introduces almost a
1% error at 82.5 deg.

And remember, that's the net current, i.e. the current in the standing
wave. It, as a net stand alone entity, is not flowing anywhere. It is
merely the phasor sum of two traveling waves traveling in opposite
directions. The phase of the forward current and the phase of the
reflected current are changing in the normal traveling wave manner.
But since their phases are rotating in opposite directions, their
net phasor sum results in very little phase shift. In fact, Kraus
shows zero phase shift for the standing wave current on an
infinitesimally thin wire.

Almost 1%! Holy moly!

You're correct that the distribution is only approximately triangular. But since a difference between a full quarter sine wave and a true triangular distribution results in less than a 0.5 dB difference in field strength, a 1% difference between a true triangular distribution and the end of a sine wave will make a difference in gain, efficiency, or feedpoint impedance that would be entirely negligible and in fact impossible to measure. For that matter, the current distribution on a wire of finite diameter isn't really a sine wave anyway, but a close approximation (although very possibly not within 1%). So the current distribution on a short antenna is triangular for any practical purpose.

Heh, heh, the helix feature in EZNEC shows the same thing. So here's
a question for all the "constant current" gurus. How can the current
in the middle of the loading coil be a greater magnitude than the
current at either end?

Hint: it happens all the time in distributed networks. I can design
an antenna with a loading coil that has one amp at one end and zero
amps at the other end. The forward current and reflected current
are simply 180 degrees out of phase at the end where the net current
is zero and thus a current node (minimum) is developed.

A naive person would say one amp is flowing into one end and zero
amps is flowing out the other end. But standing wave current doesn't
flow. This is W8JI's basic mistake in his explanation on his web page.
The standing wave current is an artifact caused by the superposition
of two traveling waves, traveling in opposite directions at the speed
of light. For a 1/4WL antenna, there is a standing wave current antinode
at the feedpoint and a standing wave current node at the tip of the antenna.

I hope most readers can tell the difference between an approximation or simplification that we understand and that produces negligible and unmeasurable errors, from one that's based on invalid premises and leads to major errors.

Fact 1.

Any loading coil of finite length contributes towards to the total
radiation.

Fact 2.

The input and output currents of a loading coil of finite length are always
different from each other.

Fact 3.

The radiation pattern of a short vertical is fixed and remains independent
of the location/height of the loading coil.

Fact 4.

Computer programs do not tell gospel truths. They are at least as
unreliable as their human programmers.

Now I understand the confusion. I am not using EZNEC, and am not familiar with the program. My analysis is written in NEC code. I do have access to some graphical results with the use of NEC-Win Pro, but have taken the NEC output file and imported it to an Excel spread sheet (NEC-Win Pro's simplified data entry formats do not recognize cards such as 'GH" and "GM" so am forced to resort to direct code entry). For a constant power input I therefore have to read the input impedance results, then calculate the required "Peak" Voltage for the desired power -- note that NEC requires all voltages and currents to be peak values.

If anybody is interested I have uploaded the models to my wife's business web site (she will probably kill me when she finds out!). The models show the current distribution of two 84" monopoles; one of which is loaded with a 6" long, 12 turn helix, of 2.5" diameter. The other is unloaded. The ground is defined as "Perfect". The input power is set at 100 W. Just looking at the curves led me to the (mostly) wrong conclusion (verified with numerical integration of the Excel data) that the Integral of I(z)dz is a constant. The results are posted at www.carolyns-creations.com/ve6cb

Regards,

Frank

# 1900. Re: Current in loading coil, EZNEC - helix

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-06 13:55:34 UTC
From: Frank <ve6cb@NOSPAM.telus.net>
Message-ID: <qJ4jd.64644$E93.34211@clgrps12>
Source record: 86995

As mentioned in an earlier post. I have analyzed an 84" monopole, at 21.3 MHz, with and without loading coils. To view the graphical results of current distribution go to www.carolyns-creations.com/ve6cb These data are placed without comment, since I cannot intelligently add to the ongoing arguments of current distribution.

Regards,

Frank

> decrease (drop) across a point.

By 'point' I believe you are referring to what is commonly referred to as a node. Kirchoff's current law stipulates that charge may not accumulate at nodes. Therefore by definition, any feature of the system where charge accumulation needs to be considered is not a node. This makes sense since charge must accumulate on a surface (surface charge density) (coul / meter squared) or in a dielectric volume (volume charge density) (coul / meter cubed). Both concepts require some sort of area or volume which is inconsistant with the notion of a node.

>I don't know anyone who disagrees with
> that so any argument is just a straw man. Kirchhoff never said the

The currents through two nodes connected in series, without branches, is identical. I think that fact was established before Kirchoff but it's certainly stipulated in circuit theory.

> Many patches have been added to the DC circuit model to try to adapt

Huh?

>Saying that
> the E-field voltage drops but the H-field current doesn't drop is

> simply nonsense.

Saying the electric field voltage drops is nonsense. Voltage is the scalar potential defined as the electric potential difference between two points in space.

The electric field is vector field, characterized as having a field strength in volts per meter dependant on spatial location, direction, and perhaps time.

I don't understand what the term 'E-field voltage drop' could mean. Same with 'H-field current drop'.

>Likewise, saying that the H-field current flows and
> the E-field voltage doesn't flow is nonsense.

H-field current flows?

The field H (amps per meter), is the so called magnemotive field. It doesn't flow anymore than voltage flows through a resistor, and is associated with the generation of magnetic flux. The magnetic flux density, B, has the units of webers per meter squared and can be integrated over an arbitrary surface to evaluate the total magnetic flux passing through that surface. Magnetic flux is somewhat analogous to current but H is not at all.

The E-field and H-field
> are usually inseparable.

In the classical electromagnetic model, E & H are completely separable. They are coupled via Faraday's law, and Maxwell's so called displacement current. At steady state (DC) no coupling exists. When one field quantity _varies_ in time, so will the other in accordance with the curl equations. The coupling described by the time varying part of the curl equations only involves the time varying components.

When determining the analysis method used to gather insight into a physical system, one of the first considerations is to determine if the time varying field components need to be considered, and if so, which ones. For example, analysis of a 60 Hz power supply choke, or electric motor, usually ignores the electric field in the air gap arising from the time varying magnetic flux density. It's not important in the gap, but is the driver of undesirable eddy currents in the core laminations.

It follows that if you choose not to make an effort to understand a
valid premise, according to you, it is still worthless.

Do standing wave antennas possess standing waves? (no answer) Kraus and
Balanis say "yes". Are those standing waves composed of forward and reflected
waves? (no answer) Kraus and Balanis say "yes". Why does Kraus say that, for
purposes of conceptual discussion, we can consider those waves to be equal?
(no answer) If it's good enough for Kraus, why isn't it good enough for you?
(no answer) Do you actually disagree with Kraus? (no answer) Why does Balanis
state that standing wave antennas can be conceptually analyzed by representing
the forward current as If and the backward current as Ib? (no answer) All I have
done is follow Kraus' and Balanis' suggestions. You finding fault with that is
amazing.

Conceptual solutions are very often not quantitized. "The sun is
the center of the solar system" is a conceptual solution and was
not quantitized for many, many years. What I have been saying is
based on what Kraus and Balanis wrote. There is no "major error"
because it is just a concept akin to lossless lines and ideal
inductors.

And just how do you explain the fact that your very own EZNEC agrees
with me when the loading is done by the helix method or the series stub
method? Sacred cows die hard, huh?

# 1907. Re: Loop antenna electrostatic shields

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-06 16:35:15 UTC
From: Tom <noname@noprovider.nodomain>
Message-ID: <737jd.409$sD1.183@trnddc02>
Source record: 87001

The 'slit' in the shield allows a voltage difference to exist across the
slit.
If there were no voltage difference, then you could short the slit with
no change in performance.

Thus the shield acts like a short dipole, with the ends bend up to almost
touch one another. There is a voltage gradient along this short shield
(dipole),
and current flow along the length of the shield (dipole).

The loop inside the shield thus is coupled to this short dipole. Multiple
turns of the loop 'add' (increase) the voltage since the dipole (shield) is
short compared to the wavelength.

Thus, the shield IS the antenna, and the loop is the means to couple the
energy out of the short dipole. Thus, it really isn't a magnetic antenna at
all - it's a dipole!

Tom, W8JI has a better, more detailed explanation at his website (a great
resource) at http://www.w8ji.com/magnetic_receiving_loops.htm

Reg Edwards wrote:
> The input and output currents of a loading coil of finite length are always
> different from each other.

There's hardly any "input and output currents" for a loading coil in
a standing wave antenna. That concept is why W8JI is in trouble with
his explanations. What is actually being measured is the magnitude
of the standing current wave.

There is forward current flowing into the bottom of the coil and out
the top. There is reflected current flowing into the top of the coil
and out the bottom. The net current is a standing current wave. If we,
as Kraus suggests, assume that the forward current equals the reflected
current (relatively small error in doing so) then there is zero net current
flowing in and out of the coil. The standing wave current is, well, just
standing there and is not "going" anywhere.

The gross error that a lot of people are making is that standing
wave current flows. If the forward and reflected currents are equal,
as Kraus assumes for purpose of discussion, then there is zero net
current flow through the coil. Yet, net current is what everyone
is measuring. What they are actually measuring is the value of
the standing wave current at each end of the coil and it is not
flowing. It is only an artifact of the superposition of the two
waves that are flowing.

The magnitude of the reflected current can be estimated from the
feedpoint impedance. The lower the feedpoint impedance, the closer
in magnitude is the reflected current to the forward current. For
a center-loaded mobile antenna, the reflected current through the
coil appears to be well within 5% of the value of the forward
current.

And when it was, the "conceptual solution" was shown to be in error.
The center of the solar system is a point about which the mass of the
sun AND the planets all turn. The difference is miniscule but such
differences being ignored would result in navigational errors in
traversing the solar system - which is Roy's point about the
significance of error being ignored where it is important.

> certainly stipulated in circuit theory.

Let's deal with concrete examples. Assume a lossless, unterminated transmission line. Because of the standing waves, the net current in that series loop varies from point. It is zero every 1/2WL and in between those zero points, it is at a maximum. That's all I was trying to say - that the series current in a distributed network with standing waves is not constant because it no longer can be considered a "circuit". It must be considered a network as it is an appreciable portion of a wavelength. The phases of the forward current and reflected current are rotating in opposite directions which causes their superposition magnitude to vary from minimum to maximum. The magnitudes of the forward and reflected traveling wave currents can be constant while their phasor sum varies as a standing wave sinusoid.

Most of the stuff in this posting is a diversion away from the original argument which is: Does the current through a 75m bugcatcher vary from end to end? Since the net current is the standing wave current in a standing wave antenna, it is mostly standing wave current, not traveling wave current. Kraus even suggests that we can consider the forward current equal to the reflected current in a standing wave antenna for purposes of conceptual discussion which means the net current is not moving at all, i.e. not flowing into the bottom of the coil and out the top as assumed by W8JI on his web page. Balanis clearly states that a standing wave antenna can be analyzed based on the forward current and the backward current.

Simulations with EZNEC using the helix option indicates that the net current is not the same at each end of a bugcatcher coil. Essentially the same result occurs using a series inductive stub.

Being such a nickpicker, why don't you object to the gross errors
(50%) introduced by using the circuit theory math model on a distributed
network problem?

# 1915. Transmission Lines & Electrical Code

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-06 19:18:00 UTC
From: gibberdill <gibberdill@bak.rr.com>
Message-ID: <Ir9jd.44017$hN1.34919@twister.socal.rr.com>
Source record: 87010

I have a new house and my main concern is not having my homeowner's
insurance nullified in the case of fire because of my ham radio setup.

I have regular coax running 100 watts through the attic.

1)Is this a violation of the National Electrical Code?

NA4G wrote:

"The National Electrical Code requires 4 inch creepage distances
and clearances between any transmitter conductor inside the building
and normal interior electrical lines. It also requires 2 foot clearance
between antennas and leadins and any other electrical lines outside.
It also requires 3 inch creepage and airgap distances beween the the
antenna and leadin lines and any building surface. The requirement
for the ``insulating support'' is nonabsorbent treated pins or brackets
with insulators having not less than 3 inch creepage and airgap distances.
(reference N.E.C. Section 810)."
( From: Robert D. Keys (rdkeys@seedlab1.cropsci.ncsu.edu)
Subject: Re: best stand offs for ladder line?

Newsgroups: rec.radio.amateur.antenna
Date: 1998/04/02 )

I may wish to go to higher power, maybe 1000 Watts and run ladder line (450
Ohm window-line) outside the house.
3-inch standoffs outside the house are a cosmetic problem.

2) Is there a safe way to run the ladder line through portions of the attic?
What about housing it in 1" PVC pipe and maintaining at least 4 inch
creepage distance within the attic? Is PVC prohibited in the attic?

3) If a 3-inch airgap distance is required between the leadin lines and any
building surface, wouldn't that require at least a 6-inch hole in the wall
of the building to bring the line in? There must be another explanantion...

I'm sure this sort of thing has come up in the past!

Frank, I don't know, and it doesn't matter, how you produced the amperes versus height graph which beautifully displayed itself with a single mouse-click on my computer screen.

It displays the curve-shape which any properly educated electrical engineer, or amateur with any intuitive common sense, ought to expect. Thanks!

The many reams of heated arguments which have appeared on this newsgroup have been a disgrace to the profession. Yes, I know its an amateur mewsgroup but the (aggressive?) contestents are mostly so-called professionals.

Clearly you have chosen an adequate mathematical demonstration model with the ability to use it. Most likely without any thoughts about Terman or theorem-writers Thevenin and Kirchoff, etc., who personally I have hardly ever heard of.

If you have not already done so, may I suggest you include radiation resistance in the model for slightly greater accuracy. It may remove the small kink in your curve which occurs immediately at the bottom end of the coil. I don't think it should be there. But further elaboration is hardly worth the effort.

I also think its a good idea to base demonstration models (like actual experimental measurements) on the lower frequencies. Try the 160 metre band. They are likely to be more accurate representations.

Frank, if you have the time to spare perhaps you should contribute to this newsgroup more often. Improve its already good entertainment, even educational if sometimes confusing, value!

By the way, I'm on Dourthe No.1, Bordeaux 2001, tonight. French politics go down very well with their excellent wine and British very mature Cheddar cheese.

Hic!

Ah, I see, modern high-technology smokeless and odorless powders do not betray your postion to the rattler if you miss him first time.

At night, have you tried infra-red telescopic sights?

But by now rattle snakes must be becoming, like Bengal tigers and red indians, an endanged species. ;o)

Hi, Silvio -

I am not very good at antennas and such, but I'll give it a shot.

EZNEC says a delta loop fed at the vertex (at the bottom) appears as about 122 Ohms at resonance. You could use a 1:1 balun and a quarter wave piece of 75 Ohm coax and then 50 Ohm coax for the remainder of the trip to your transmitter. At the 75/50 Ohm point your impedance would appear as 46 Ohms. This would give you an SWR of about 1.08:1.

If you do not have 75 Ohm coax, you could instead insert an open stub of about .381 wavelengths at about .159 wavelengths below the balun using all 50 Ohm coax.

And then there is the possibility of using open wire line with a tuner.

Hopefully, I did all this correctly. If not, I hope someone else will jump in here and correct me.

Good luck.

John

> creepage distance within the attic? Is PVC prohibited in the attic?

unfortunately i don't have a copy of the code at home and don't often use it
for this type of stuff anyway. but if the creepage distance is what i seem
to remember, that is the length of the insulating standoff that is holding
the wire. so no, putting it in a 1" pipe wouldn't work, you need to have a
3" or 4" creepage length insulator.... creepage length if i remember right

is measured along the surface of the insulator, so if the surface has grooves or ridges it is actually longer than the straight line length. hard to explain, but it measures the length a current would travel if there was dirt or moisture on the surface of the insulator. the requirement for a 3" airgap would mean you need at least a 6" + wire spacing conduit with the wire held in the center by appropriate length insulators.

>
> 3) If a 3-inch airgap distance is required between the leadin lines and any
> building surface, wouldn't that require at least a 6-inch hole in the wall
> of the building to bring the line in? There must be another explanantion...

yeah, except as noted above, if the wire spacing is 1" for the ladder line the hole would be 7" by 6"... great fun these codes aren't they!

:-) Balanis is my Arizona State University professor who directed
my thinking along these lines. He's the author of a textbook titled:
"Antenna Theory, Analysis and Design" that has come to be a later
reference than some of the Kraus, Jasik, Terman stuff. You can
obtain a copy of his book on Amazon.com for only $119. A web
search for "Constantine A. Balanis" turned up three pages of
lists of web pages.

Unless you intend to run 10 kilowatts of RF power, try to completely forget all about your hopelessly imagined problems. Don't lose any sleep. Just use ordinary electric wires and cables and run them wherever you fancy. Just like domestic 110-volt power cables.

I've been running 100 watts over 20-gauge plastic insulated wire through 1/8" holes in dry, inflammable, wooden window frames for nigh on 25 years and never yet burned the house down.

For Auction up on eBay is an essentially new Diamond X2200A base antenna.
This is a 144/220 base station vertical that is about 8 ft long. Assembled
it and put it on the roof for a few hours to test. Took it down and put it
back in the package so it's almost new.

http://cgi.ebay.com/ws/eByISAPI.dll?ViewItem&rd=1&item=5729169943&ssPageName=STRK:MESE:IT

Auction ends sunday night. Presently at $59

Thank you for your reply.

Actually, I am not afraid that I will start a fire.

I am afraid that a fire might start for some other reason, and that my insurance company won't pay my claim because of unrelated code violations.

So again, let me ask:

What must a homeowner do regarding ham transmision lines so as to avoid code violations?

W5DXP wrote:
>>There is forward current flowing into the bottom of the coil and out the top. There is reflected current flowing into the top of the coil and out the bottom. The net current is a standing current wave.<<

In view of the above, for practical putposes, trying to get maximum performance out of the loaded radiator, it should be beneficial to have the same diameter of whip above the coil, rather than tapering whip?
One might deduct that if the current is diminishing towards the top, that the diameter of the radiator (RF resistance) could be tapered also. But since the RF current has to flow to the tip and then reflect and go back and interfere with itself, we should make it uniform, where possible.
We are probably talking about fraction of a peanut, but for the purists and sake of argument.

Fact 1.

Any loading coil of finite length contributes towards to the total
radiation.

NEWSFLASH - there's no such thing as a perfect inductor. Amazing!

Fact 2.

The input and output currents of a loading coil of finite length are always
different from each other.

A natural consequence of fact #1.

Fact 3.

The radiation pattern of a short vertical is fixed and remains independent
of the location/height of the loading coil.

Not so, precisely because said inductor cannot be perfect. HOWEVER, the
difference is neglegible and probably immeasureable.

Fact 4.

Computer programs do not tell gospel truths. They are at least as
unreliable as their human programmers.

Ahh, but at least they are *consistantly* unreliable in predictable ways,
which is more than can be said for humans.

The requirements for amateur radio stations are in Article 810 of the NEC. My copy of the NEC is 14 years old, so I wouldn't want to quote it. A google search of

NEC 810 amateur

produced quite a few hits, some with direct quotes from the NEC. I suggest you take a look at a few of them. Considering how seriously you take the matter, and the possible cost of doing it wrong, I don't think you should depend on newsgroup answers to your question. You should see for yourself just what the NEC says.

I also suggest that you contact your city, county, or state electrical inspection department. It's possible that one or more of those jurisdictions have requirements differing from, or going beyond, the NEC. They also might have a copy of the NEC and local codes that you could look at and/or photocopy. And, they should be able to answer any questions requiring interpretation.

If your electrical inspection office can't provide a copy of the NEC for you to look at, you might consider shelling out $100 - $200 to buy one. It doesn't change much from year to year, so you might be willing to settle for a previous year's copy which I'm sure you can find at a substantially reduced price. Or, excerpts might be available at a lower price yet -- a web search would be the best way to find them.

You can download a free demo version of EZNEC from http://eznec.com.
It's perfectly adequate for analysis of simple antennas with lumped
loads, and gives you full graphics, the ability to fix the power level,
and all the other features of the full EZNEC program with the single
exception of a 20 segment limit.

The demo version also includes the full EZNEC/EZNEC+/EZNEC pro manual,
and there's no time limit on its use.

I'm aware that the PL-259 has loss but what I'd
like to find out is how much loss at 146 & 450 mHz?

Anyone know?

Ken KG0WX

It depends on a whole lot of factors, not least of which is the quality of the connector and how accurately it is assembled. For 70cm, losses are typically around 0.7 - 0.8 dB. This might not seen like a lot until the number of connectors is added up.A base station with a main co-ax run, a socket terminated antenna, and 2 co-ax tails has 4 connections. That adds up to 3dB, or half your signal lost before you even look at the co-ax losses. By comparasion, a quality N-type is less than 0.1dB.

True for practical purposes. People using antenna modeling programs, or people adept with analytical techniques, will find a small difference in pattern as the loading coil is moved, due to the changed current distribution. But it's an inconsequential difference.

That doesn't help much. What helps is a humongous top hat which does
help to equalize the current at the bottom of the coil and the current
at the top of the coil.

Nope, not a fraction of a peanut at all - more like 100% more radiated
power because of that humongous top hat. I'm considering a humongous top
hat for my pickup that runs the length of the truck and is mounted about
a foot above the cab - maybe 50 square feet in all. That would minimize
the size of the loading coil and ensure maximum current in the bottom
section. The maximum height above ground would be about seven feet, a
definite advantage for a mobile antenna around here.

I don't see what the mechanism would be for the 0.7 - 0.8 dB loss you quote, even if the connector has a rather poor dielectric. And one with a good dielectric like Teflon wouldn't have any way to cause loss other than conductor skin effect resistance. If anything, I'd expect an N type connector to be slightly (although inconsequentially) lossier due to its smaller diameter center conductor.

What reference do you have that shows this kind of loss for a PL-259? I'd like to look at the test methodology. I'd also like to hear some kind of explanation as to why an N type connector should have less loss than a PL-259.

A PL-259 will of course cause a greater reflection than an N type connector, and this will produce a "mismatch loss" in a system, like a lab test environment, where the source and load impedances are fixed. But nearly any amateur antenna installation has some method of adjusting the match to compensate, which eliminates power delivery reduction due to mismatch. Then, only true loss is important, and I just don't see the mechanism which would cause a PL-259 to be any worse than an N.

The ARRL hand book has a few paragraphs on this. It seems that if the coax is grounded you are ok. If not coax then the wire needs to be sujpported 3 inches from the walls on insulators and comes into the building through an insulated tube.

# 1949. Re: please need help with delta loop antenna better matching system than gamma match

Sylvio,

I use full wave delta loops on 30 meters and 40 meters. To match them I use a 1/4 wave 75 ohm feedline. (multiplied times the velocity factor of the coax - about .81)

So, from the back of my radio I have a random length of RG/8 50 ohm coax. Then I insert a 1/4 wave of 75 ohm coax to the antenna. This works quite well for me and results in SWR of 1.1:1.

>
>

Looks like another "debunked" fact by "Tom noname" W8JI.
(Welcome back Tom ?:-)

The shield IS an electrostatic SHIELD and wires inside are the ANTENNA.
If you want good efficient, electrostatically shielded small loop, take copper or aluminum tubing, bend it in a circle about 1m diameter (for around 160m band). I made it of two pieces, joined at the bottom in metal electrical box. Top of the loop is open and insulated with plastic tubing. Then thread wire through the loop, three turns, bring the ends into the junction box and connect trimmer capacitor (about 1.5k ?) across the ends (not connected to anything else). Then thread another single turn loop through the tubing. In the junction box, connect one end to the coax shield and the second end to trimmer capacitor (about 500 pF ?) in series with the center conductor of the coax. Shield and mast holding it can be grounded at the installation place. I actually used low power transmiter and SWR bridge to tune the loop, now there are nice antenna analyuzers to do it.
The three turns are resonated to operating frequency with capacitor and that is the ANTENNA. The single turn loop is the coupling and trimmer provides match to the coax feedline. The tubing is a SHIELD which helps with suppressing the noise and interference from nearby sources.
I have also used this loop as a coupling to Beverage antenna (positioned at the end of Beverage), where it provided less noise than beverage alone.

Don't believe everything you read at W8JI web pages.

I would like to see a short "dipole" (NOT), really short piece of tubing, which is attached to a mast and grounded to act as an antenna on low frequencies. Having small loop, insulated and properly fed or coupled to, is another thing. You can have single loop or turn antenna too, but above described antenna is "magnetic" or electrostatically shielded small loop antenna which provides more signal and better discrimination from nearby interference.

# 1951. Reflectors For H.F. use

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-07 02:21:14 UTC
From: "aunwin@insightbb.com"
Message-ID: <uEfjd.579123$8_6.52336@attbi_s04>
Source record: 86946

For ham radio it is conventional ( my thoughts) to see reflectors as element/s placed behind
a feed element where. like other elements in an array receive radio energy and then reradiate a portion of the received energy.If one wants to emulate a point
radiation then many elements have to be arranged in parabolic fashion such that all R.F.
received or transmitted meet at a common point.

Now I really know didly ######about dishes as my world is made up from Yagis but now
I am starting to think about these things which really raises questions about what I had previously accepted
For instance,
1
Commercial dishes are not made of reflectors with a fraction of a wave length ( surface is smooth)
So we have some how shifted from 'resonation' to a 'reflection' mode as in light even tho a resonance
must still some how occur, but how and with what length reflectors ( multiple long wires?)?
2
If radiation/reception follows a common path then is the dual path radiation as seen with a Yagi (90 degrees apart)
changed ?
3
What would the result be if multiple electrical connection lines were made between the horizontal reflectors (vert refl form)?

The emergency operation is now over after a lousy week in hospital but I am grounded for the rest of the year
( pain and infections and physical inabilities) books and the like is a hard task but the laptop is at hand if I can find suitable links to study.

Plans are complete and parts available for a 20 metre dipole with eight reflectors set in quasi parabolic form to deliver
14.5 dbi.BW 63 degrees which I hope then to reduce to 30 degrees for added gain.
Feed dipole will be of variable length for different band use.
Isn't experimentation great when failure is not considered disasterous to ones self esteem and resume?

Regards
Art

For this progression, I have amended the design through the addition
of 1 wire, 20M long, 21 segments, Vertically polarized, center loaded
with a 73 Ohm Resistor, 4000M remote from the test antenna, and
elevated 2127M to sample the radiation lobe at an angle of 27ï¿½ which
represents the Best gain angle from previous results (or nearly so).

I further perform readings of the 73 Ohm load under two conditions of
the test antenna. Those conditions are when it is excited by 1A (the
constant current mode) and when it is excited by 36.65W (the constant
power mode). I also include the power into the antenna for the
constant current mode.

>appreciate other effort in kind to correct any oversights I've made
>(not just the usual palaver of tedious "explanations" - especially
>those sophmoric studies of current-in/current-out).

Well, now we can review this data in light of my previous
editorializations.

We begin with the premise that Rr is evidenced by the power expressed
by a known current through an unknown (Rr) resistance. We needn't
concern ourselves with the constant power mode as it closely mimics
the former data. In essence, it serves as a validation of the two
models (the previous post and this post).

However, the constant current mode does show a variation in power
received at the sniffer antenna. For a shorter antenna, there is a
corresponding fall in the power. Counter to my editorial observations
above there is an increase in this power received at the sniffer
antenna when a load is applied. The contrast in my former editorial
observation and this data reveals that Yes the Rr is impacted by
loading and that the drivepoint Z is the Rr.

This comes as no surprise to many.

Now, let us return to a point of analytical bias that lead me to
believe no apparent change in Rr was observable. In fact there was no
way to make it observable except through the artifice of my sniffer
antenna. For the model of the constant current generator, it is a
truism that gain (that is true gain for a system and not simply
antenna directivity) must increase for the same excitation. After

all, we are changing the Rr either through the actuality of modified length, or the artifice of a moving, variable load along the short radiator. Such gain is only observable through a circuit (broadcaster lingo for a transmit/receive pair).

In the back of my mind I was troubled about comparing situations in dBi. Yesterday I expressed this as a possible source of confusion for the effects sought in evidence against the obvious gain differential. dBi is a dimensionless relation such that true gain is washed out of the result. When I attempted to confirm my suspicions through field expressions of mv/M for 1KW, I was struck that that too forced the results to a constant power (not constant current) and thus hid the gain demonstration in the same way. I then fell back on my practice of employing a sniffer antenna to test reality and the data is found above confirming the gain that would be expected. In other words, the far field's power followed the diminution of Rr with a positive correlation. It also followed the subsequent increase of Rr (with a load applied to that shortened radiator) with a positive correlation.

Thanks for your comments Reg. The fact is my graph is produced in Excel from data provided by a NEC 2 output file generated by few trivial lines of NEC code. I cannot claim to have done anything requiring much thought. I just considered, since so much discussion is centered on current distribution, that some might be interested in the posted curves. So far yours is the only response. I will probably delete the page in a day or so. The loading inductor is 2.5" diameter, 6" long, with turns spaced at 0.5". The NEC code is listed on the site, so anybody can copy to verify the validity of my results -- or the validity of the code.

I have included a conductivity for copper (5.8001E7 S/m), and since the ground is defined as perfect, this accounts for all losses within the model. The program predicts the total radiated power as 95.918 W from 100 W input. The input current is 2.3874 A RMS, and input impedance 17.545 Ohms. The radiation resistance is therefore 16.829 Ohms. (Sorry for all the decimal places, but they produce such nice round numbers). I was also puzzled by the slight increase in current just under the loading coil, but suspect it was caused by coupling between the lower conductor and the base of the coil.

I agree that some experimental data would be good. I have been planning for some time to erect a 160 m vertical, so can see how the predicted results compare. I have also used your software for modeling verticals, and it is in very close to the results produced by NEC. The one problem with NEC 2 (Though not with NEC 4) is that it cannot model buried radials, but can get very close to the ground.

I don't mind an occasional post on this news group, but not sure I can contribute much. I do enjoy reading other people's posts though.

I sure could enjoy a glass of wine with cheese, but have nothing much in my fridge -- except for some old Cheddar.

Regards,

Frank

Don't believe everything you read here, either. For a good treatise on how the shielded loop works, and what it's good for, read Glenn S. Smith's (Georgia Institute of Technology) article "Shielded Loop Antenna" in Richard C. Johnson's _Antenna Engineering Handbook_.

My results, all around, did not require perfection, and in fact,
nothing was resolvable through perfection if you would review that
recent post.

>As an old (sorry [g]) metrologist, you're very familiar with
>substitution, so let's set Rl = 0 (lossless case) and eta to 0.5 (-3

This old metrologist found the very simple answer that eluded others
who simply took it on faith and stumbled for reason. My substitution
resolved the situation (aka the sniffer antenna which served admirably
to function as what you would appreciate as a "transfer standard").

>So in our model, if I add a simulated ground resistance, Rg, that

It is all about keeping things in phase. The parabolic dish just reflects
the signal such that the phase at the feed is the same (or time delay) You
can say they resonate, or have high currents but if an element is 1/4 wave
away. it will pick it up. There some cross bread antennas between dishes and
Yagi too. mostly in 1 to 2 G band.

Good luck with the health. Phase is the name of the game, they use phased
towers at AM band to switch the pattern around from day to night, usually
you will see 6 in a rough circle, all 50 to 150 foot high.

Thomas Edison referred to failed experiments as ways of 'eliminating' the
things that don't work.
So a failed experiment is not a failure at all.
But its a lot more fun when we find things that DO work !!

==========

The only program I am reasonably familiar with is the several years old free EZNEC. I don't know whether it has been updated or not and I make very little use of it. Come to think of it, I don't make much use of my own programs either.

Regarding shallow buried radials in conjunction with a vertical, have you tried my recent program RADIALS2 ?

It is intended to demonstrate performance of the radials themselves in a given ground rather than antenna performance. Which I suspect is the reverse of NEC-4.

As you probably know, the effects of above-ground radials change very rapidly as they get within a few inches of the ground surface. But once in the ground they tend to remain static.

RADIALS2 uses an entirely different, unconventional form of performance analysis. If other programs don't take soil permittivity into account at HF, predictions must lose accuracy. Are the inputs and outputs of NEC-4 in a form suitable for a direct comparison with my simple program?

But in view of the large uncertainties involving ground conditions, accuracy is not worth making much of a song and dance about.

> antenna directivity) must increase for the same excitation.

The difference between gain relative to isotropic (which you're unnecessarily calling "true gain") and directivity is only the efficiency. If loss is zero, the gain and directivity are the same. If there's 3 dB loss, for example, then the gain relative to isotropic is 3 dB less than the directivity.

I need to insert a reminder here for readers who aren't as familiar with the terms as some of the rest of us. There isn't a single value of gain for any antenna. First, it's nearly always different in different directions. Second, the gain depends on the reference antenna, so you can have just about any gain you want, just by choosing the reference. EZNEC, NEC-2, and most professional publications use a theoretical isotropic antenna as the reference, resulting in gain in dBi. The main reasons for this are that it's unambiguous -- everyone agrees on what it means -- and it makes it easy to calculate field strength from gain and vice-versa.

Now, back to the comments. . .

It isn't true that the gain must increase as Rr increases, when the source is a constant current. The gain relative to isotropic (reported as dBi) is defined as the field strength from the antenna divided by the field strength from an isotropic antenna *having the same power input* -- converted to dB of course. As the Rr increases in your model antenna, the power input increases if you're using a constant current source, as you've pointed out. But the power input to the imaginary isotropic comparison antenna increases by the same amount. The net result is no change of gain due to the increased power input, or to the increased Rr. What you're measuring with the "sniffer antenna" isn't the gain -- it's the absolute field strength. To get the gain, you need to compare that with the field strength you'd see if you applied *that same power* to an isotropic antenna the same distance away. You should find that the power

dissipated in your sniffer antenna load is directly proportional to the power applied to your transmit antenna. That would also be true for an isotropic transmit antenna, so the ratio of power received from the two antennas will stay the same as you change the transmit antenna power.

As I pointed out before, moving the load in the transmitted antenna changes the current distribution, resulting in a very small change in pattern shape, hence a very small change in gain. But that's the only effect it has on gain.

> After
> all, we are changing the Rr either through the actuality of modified

> for the effects sought in evidence against the obvious gain
> differential. dBi is a dimensionless relation such that true gain is
> washed out of the result.

No, dBi is the "true gain" expressed in dB, as explained above. It's the field strength from the antenna compared to the field strength from an isotropic antenna having the same input power. Simply increasing your constant current source from 1 amp to 2 amps will increase the signal detected by the "sniffer antenna". But I hope you can see it's not changing the gain of the transmit antenna.

> When I attempted to confirm my suspicions through field

> the far field's power followed the diminution of Rr with a positive
> correlation. It also followed the subsequent increase of Rr (with a
> load applied to that shortened radiator) with a positive correlation.
>
The source of confusion or misinterpretation seems to be due to mistaking field strength for gain. They're not the same thing. Even the units are different -- Volts/meter or Amps/meter (or power density in watts/square meter) for field strength, while gain and directivity are dimensionless.

Gain would be a much less useful measure if it changed with power input. Then, we'd have to specify the power input at which the gain is measured. EZNEC correctly shows no gain change resulting from changing the input power. As it is, it's easy to calculate the field strength at any point in the far field from the gain in that direction, power input to the antenna, and distance from it. In fact, EZNEC and NEC-2 actually compute the fare field strength, and then derive the gain in dBi from it

by knowing the field strength from an isotropic antenna with the same power input. Gain relative to isotropic becomes less useful in the near field, so absolute field strengths are generally used in that region.

That's because your graph embarasses that half of the contestants who insist the coil's input and output currents are identical and so the less said about it the better.

And it gratifies the exhausted sentiments of the other half who are unwilling to grant you the credit for providing the convincing evidence after all the hard work they have put into stating the bleeding obvious. And still are.

(After John Cleese who joked about the value of the distinction of a first-class university honours degree in stating the bleeding obvious.)

Neither was there was any response to my brief statement of 4 Facts except yours. And for similar reasons. I did not expect any response. But after all, any unsupported statement of mine (no Terman, no Kirchoff, no Kraus, no Thevenin, no Balony) can hardly be construed as evidence of anything.

The value of the shield on a small loop is an overated old-wives tale.

Having erected it, performance would be better to use the shield itself as the loop, by virtue of its much greater conductor diameter.

calling the longer element 'behind' the driven element of a yagi a
'reflector' is poor terminology. it does not actually 'reflect' it just
resonates at a slightly different point and the combination of phase and
distance from the driven element contribute to the gain in the 'forward'
direction and cancel out signals in the 'backward' direction. actual
reflection requires a conductive surface several wavelengths long in all
directions as is done on parabolic dishes for microwave use. even when you
look at vhf/uhf yagi's that have multiple reflectors they are still only
using the phase shift of the resonance of them to add or cancel energy from
certain directions. the smallest one that might be really called a
reflector is the 'corner reflector' antenna sometimes used at vhf and uhf.

Hi Frank, your results look reasonable and thanks for your input.

> I was also puzzled by
> the slight increase in current just under the loading coil, but suspect it
> was caused by coupling between the lower conductor and the base of the coil.

A number of us have reported the same thing. In my EZNEC octcoil.ez simulation, (available from my web page below) the net current decreased by 2% from the feedpoint to the coil and then in the first part of the bottom of the coil, it increased by 5%. (Whoops, I almost said it "dropped" by 2% and "rose" by 5% which would have elicited endless nitpicking. :-)

There is, no doubt, an impedance discontinuity at each end of the coil. The net current standing-wave values at each end of the coil that differ from just a straight wire are probably due to interference effects among the various forward and reflected wave components. A conceptual idea of what is happening might be the following solvable example (S-parameter analysis).

```
a1--> | <--a2
<--b1 | b2-->

-----Z1-----+-----Z2-----+-----Z3-----open

bottom coil top
wire wire
```

The Z1 to Z2 impedance discontinuity will cause reflections in both directions.

b1 = s11*a1 + s12*a2 b2 = s21*a1 + s22*a2

The Z2 to Z3 impedance discontinuity will also cause reflections in both directions.

same equations as above with different parameters

The net current at the bottom and top of the coil cannot be expected to be the same as in a straight piece of wire with no step functions in the impedance.

Rumor was that Edison didn't like AC, didn't experiment much with it,
and didn't think it would work. That was good news for Westinghouse.

wrote:

|I don't see what the mechanism would be for the 0.7 - 0.8 dB loss you
|quote, even if the connector has a rather poor dielectric. And one with
|a good dielectric like Teflon wouldn't have any way to cause loss other
|than conductor skin effect resistance. If anything, I'd expect an N type
|connector to be slightly (although inconsequentially) lossier due to its
|smaller diameter center conductor.
|
|What reference do you have that shows this kind of loss for a PL-259?
|I'd like to look at the test methodology. I'd also like to hear some
|kind of explanation as to why an N type connector should have less loss
|than a PL-259.
|
|A PL-259 will of course cause a greater reflection than an N type
|connector, and this will produce a "mismatch loss" in a system, like a
|lab test environment, where the source and load impedances are fixed.
|But nearly any amateur antenna installation has some method of adjusting
|the match to compensate, which eliminates power delivery reduction due
|to mismatch. Then, only true loss is important, and I just don't see the
|mechanism which would cause a PL-259 to be any worse than an N.

I second Roy's comments.

The "UHF" connectors have many drawbacks: they are not constant
impedance, they are not waterproof, their mating is not repeatable and
they are difficult to assemble; however, they are not necessarily
lossier than other types.

It is difficult to prove this in a lab environment because there are
no traceable reference standards for this connector series. Thus,
between-series adapters are needed to measure them and adapters always
add uncertainty to the results.

Clearly though, by inspection it can be seen that for decent quality
materials and construction, there is no inherent loss mechanism that
would result in the highly inflated loss figures commonly bandied
about in ham radio circles.

Looking at my Wirebook IV, pages 3.2 and 3.3

Alan Bloom, n1al, used an HP8753 RF network analyzer to compare losses
of UHF vs. N connectors.

Both connectors measured 0 db loss up to 100 mhz.

At 150 mhz, the N has 0 db loss, the UHF has .01 db loss.

At 450 mhz, the N has 0 db loss, the UHF has .09 db loss.

That's it...

==========

Yes, I now understand.

Everything depends on your insurance company's policy on what tricks they employ to avoid paying claims. So the best place to enquire is at your insurance company.

On the other hand, the probability of the exact circumstances ever arising which would invalidate a claim is smaller than you, personally, winning the National Lottery.

All of life is a gamble. You can't cross the road without the risk of being run over by a bus. But in this particular very narrow case the odds are on your side.

And you don't want to spend the remainder of your life trying to calculate the exact probabilities before erecting your antenna. Don't keep the DX waiting! If you are still a little aprehensive, just keep a bucket of water and a bucket of sand handy in the attic.

> to what "many" think.

That's exactly what I am talking about. W8JI completely ignores the increase in current through a loading coil. How does he explain the current inside the coil being of a greater magnitude than anywhere else in the system, including at the feedpoint? (Hint: he doesn't as he apparently believes that would be a violation of Kirchhoff's laws!) But it happens all the time in distributed network configurations.

Here's a quote from http://www.w8ji.com

"How much difference is there in loading coil current ENTERING the coil and loading coil current EXITING the far end? If the antenna beyond the coil has a low self-impedance compared to the impedance of the shunting capacitance from the coil to "ground", the currents at each end of the coil will be essentially equal."

We can imply that w8ji believes that STANDING WAVE currents flow, "ENTERING" the bottom of the coil and "EXITING" the top. With a false premise like that, he cannot possibly get anything right from that point on.

However, if we accept Kraus' approximation in the following quote from "Antennas For All Applications", ZERO net current will be flowing through that coil.

Speaking of thin linear standing wave antennas:
"Current-distribution MEASURMENTS indicate that this is a good assumption provided that the antenna is thin, i.e., when the conductor diameter is less than, say, 0.01WL. Thus, the sinusoidal current distribution approximates the natural (current) distribution on thin antennas." ... "A sinusoidal current distribution may be regarded as the STANDING WAVE produced by two uniform (unattenuated) traveling waves of equal amplitude moving in opposite directions along the antenna."

The diameter of #16 wire on 10m is about 0.0001WL, beating Kraus' above approximation requirement by a couple of magnitudes. (The actual difference in the forward current and reflected current through the coil appears to

be in the neighborhood of about 5% for a loaded mobile antenna.)

Dave
So how does one "create" several conductive surfaces of what ever length
on a continuos electrical surface? My reflectors will consist of individual
elements tho I may well eventually connect them vertically at a later point.
If one should look at it in terms of phase and distance then how is the
length
of the phase changing element determined on a continuos surface?

even when you
> look at vhf/uhf yagi's that have multiple reflectors they are still only
> using the phase shift of the resonance of them to add or cancel energy
from
> certain directions. the smallest one that might be really called a
> reflector is the 'corner reflector' antenna sometimes used at vhf and uhf.

Since my wave length is long, does it really matter if the spacings between
reflectors
is :"open" for a small fraction of a wave length?
Can fields exist to deter penatration?

My cruising on the net has not provided one example of a "dish" style
antenna for H.F.
yet it would appear that there are advantages there if backyard space is
small,
especially for multi band use.
.
Surely, somewhere in ham radio history, a demarcation line for dish antennas
has been ascertained based
on advantages versus disadvantages ! If gain and f/b ( prime specs for the
amateur) can be manipulated
into higher extremes using dishes then is it reluctance to change or to lead
that dominates the hobby
based on the notion that all is now known?
There seem to be so many advantages with this aproach now that weight issues
are overcome

with foil coated fishing poles that I wonder what it is I am missing in a
much experimented field where
this portion has been pre dismissed or where coil dissertation is to prove
greater inroads in the hobby..
In this particular case I would welcome negative comments from those with
expertise in the field so
that these aspects can be given more thought,but then expertise is not a
real requirement since
so little is written.

Regards
Art

# 1983. Re: PL-259 loss rate?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-07 17:46:07 UTC
From: Roy Lewallen <w7el@eznec.com>
Message-ID: <10osnr2b4e9qs82@corp.supernews.com>
Source record: 86878

Ah, yes, he's measuring "insertion loss" in a system with fixed source and load impedances. This isn't only dissipative loss (although it can include dissipative loss), but rather is the "loss" or reduction in signal received at a fixed load. This reduction in signal is caused by the combination of real, dissipative loss and that due to mismatch between the source and load (known as "mismatch loss"). For example, if you had a piece of completely lossless 75 ohm coax between the source and load in his (typical lab) test setup, you'd measure 0 "insertion loss" if the line was exactly a half wavelength long, 0.18 dB if the line were exactly a quarter wavelength long, and other values depending on the line length. This isn't due to any loss in the cable, but to reduction in the signal dissipated in the load due to mismatch when using a fixed source impedance.

If we put a matching circuit at either end of the coax, we can make the "insertion loss" completely disappear, by restoring the impedance match. In a typical amateur antenna installation, we do use a matching arrangement to insure this impedance match. Therefore, any "insertion loss" due to mismatch is eliminated. All that's left is any true, dissipative loss. The mismatch loss VE3JEG measured is, I believe, nearly solely mismatch loss.

I've posted a fair amount on this topic in the past. You should be able to find the postings with a groups.google.com search of this newsgroup for postings by me containing "mismatch loss" or "insertion loss".

Please see my comments to Ivan's posting, about the fact that "insertion loss" is being measured in a fixed impedance environment. The same comments apply here.

Interesting that N1AL got about 0.1 dB insertion loss at 450 MHz, while VK3JEG got about 1.0. These measurements aren't easy to make, even when you have the best equipment. But as I said in my comments, they're not measuring dissipative loss anyway.

ANTENNA CONSTRUCTION MATERIALS

I use fishing poles for all my antenna experimentation.
I thought supplying the following info would be of interest
to antenna builders on this news group.
I now see fishing pole antenna manufacturing as the prime method
and not as a "make do" in place of conventional aluminum tube
construction

REASONS

ALUMINUM (aluminium for U.K. builders)
My aluminum rescources always seem to miss a required diameter.
Clamps used to secure element portions always increased susceptability to
ice build up
Aircraft style tubing increasingly expensive
Elements with electrically faulty connections.
Pre built antenna prices are now rediculous
thus new avenues are required for emerging hams.

FISHING POLE.
A 20 foot telescopic fishing pole can be used as a standard
for all types of antennas without permanent mutilation.
Cost per pole is $10 ( $2 if purchased in quantity China FOB )
Weight is 1 lb
Material fiberglass with shellac outer protection
No element clamp requirements
Taper is perfect
No ice build up.
Pre sticky coat aluminum foil rolls readily available at hardware stores.
Elements are electrically continuous as foil is applied lengthwise
Foil length does not have to be physical element length
Foil can be readily removed if required using heat gun or hair drier
Boom to mast materials need not be metallic because of lightness of element
Telescopic assemblies a breese to store.
Boom materials are more optional and plentiful
Rotor costs drop
.
LENGTH OF USE
About ten years of continual antenna experience
Temperature extremes 95 F to -20 F
Breakdown and reassembly rotations numerable.
Max number of elements used on one installation,
13 elements on a 80 foot boom.(20 metres, total element wt
was 26 lbs)

Regards
Art

Hi Roy,

Let's call it relative gain then. The point of the matter is not in terminology but in magnitude and correlation.

The Thread, throughout, is constituted of four principles:
Rr;
Current;
Radiator size;
Loading;

To reveal their inter-relatedness required an impartial witness of an external load (the remote antenna which is the raison d'etre of communication).

The gain evidenced in this remote antenna is not some arbitrary change of terms that is alien to the craft of communication (nor even the majority of engineering). It encompasses differences that exceed 1dB, eclipsing that even to the point of being 7dB in the first iteration. When in the second iteration the shortened antenna is brought to resonance, the change still exceeds 1dB (2.9dB by my reckoning). ALL such changes, when viewed through the veil of dBi simply reveal miniscule changes of what you call ground reflection. As such, dBi is a poor mechanism to reveal Rr's characteristic through structural variations.

I won't go on with the remainder of iterations because no new observations would be drawn. Indeed, the data supports the generality that suits the purpose of achieving the expected results. As I offered:

>>This comes as no surprise to many.

Now, the issue of Isotropism is one that is power centric, and this is certainly the common experience of any Ham trying to load an antenna from a real transmitter. They have a finite amount of power they wish to maximize, and this then becomes an issue of efficiency. However, there is NOTHING in my work that states this is a goal - or I would have expressed that in no uncertain terms. If any seek that divergence of issue, then my data supports it without further

qualification.

So, gain is entirely consistent within the context of the simple agenda that was explicitly described. Gain was shown to follow structural changes with positive correlation. Gain was shown to follow those changes in direct proportion. Gain was shown to be consistent with expectation. If such Gain is shown to be a wash in efficiency at best, worst for wear, or a boon to mankind, that is simply an issue of implementation and outside of my discussion of examining:
Rr;
Current;
Radiator size;
Loading.

Actually, only roughly 30% voted for him. If all the potential
voters who didn't bother to vote had voted for me, I would
have gotten more votes than Bush or Kerry. Scarey, huh?

Maybe not so scary if you had a decent platform such as "A radio in
every room and an antenna on every roof."

I usually insert a short length of plastic pipe between the two elements
(fishing poles) and then fasten to a mounting plate using U clamps.
Mounting plate material has ranged from plexiglass, light aluminum,
phenolic sheet to just plain plywood.
Actually have made my own U clamps using pre threaded rod and wing nuts
at different times since strength is not a big thing anymore.

In addition to the 75 Ohm line that people have mentioned, there are also
2:1 and 2.25:1 matching transformers. Amidon sells the 2:1, but it is
expensive, $59, as I recall. Personally, I use 1/4 wavelength of RG11, but a
transformer might be better for multiband use.

For those who want to see Al's original USENET post from 1992:

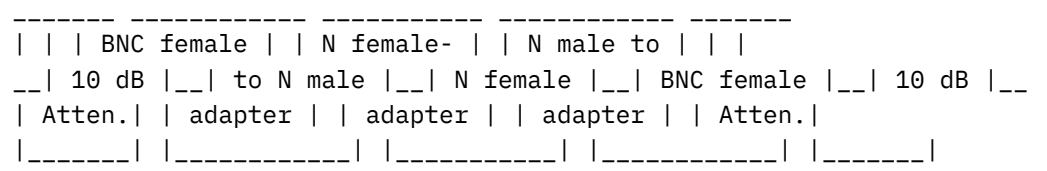
From: alanb@hpnmdla.sr.hp.com (Alan Bloom)
Date: Fri, 18 Sep 1992 23:03:13 GMT
Subject: The Truth about UHF Connectors
Message-ID: <14570492@hpnmdla.sr.hp.com>
Organization: Hewlett-Packard, Santa Rosa, CA
Path:
dxis!batman!cs.widener.edu!eff!sol.ctr.columbia.edu!spool.mu.edu!sdd.hp.c
om!scd.hp.com!hplextra!hpl-opus!hpnmdla!alanb
Newsgroups: rec.radio.amateur.misc
Lines: 64

Ya gotta feel sorry for UHF connectors. Recent strings on this notes
group lambasted them as worthless at VHF and above, and barely
tolerable at HF. One poster called them "5 dB attenuators", and
many agreed that there must be some sort of conspiracy among ham

equipment manufacturers to inflict such garbage connectors on the
amateur community.

Today I finally remembered to bring some UHF adapters from home so
I could do some relative measurements of UHF versus type-N.
As expected, the type-N showed lower insertion loss at high
frequencies, but the UHF connectors were hardly "5 dB attenuators."

For the test I connected an HP8753 RF network analyzer through
two short BNC cables into the following arrangement:



Then I repeated the measurement with the N adapters replaced with UHF.
I normalized the measurements by replacing the 3 adapters with a BNC
double-female. (That is, this was assumed to have 0 dB loss.)

Since two N or UHF adapters were used, I assume the loss per connector
is half the total. The vertical scale was .1 dB/division, so I
estimated the insertion loss to the nearest .01 dB or so:

--------- Type N ---------- ---------- UHF
------------
FREQ (MHz) TOTAL LOSS PER CONNECTOR TOTAL LOSS PER
CONNECTOR
1.8 0 dB 0 dB 0 dB 0 dB
30 0 0 0 0
100 0 0 0 0
150 0 0 .02 .01
200 0 0 .03 .015
450 0 0 .18 .09
600 0 0 .26 .13
900 0 0 .66 .33
1000 .05 .025 .8 .4
1300 .1 .05 .86 .43
1600 .05 .025 .5 .25
2000 .05 .025 .02 .01

Insertion loss increases until about 1200 MHz, and then starts to
decrease until it is almost zero for the UHF connector at 2 GHz!
At this frequency, the connectors are about 1/4 wave long (1 inch,
assuming .66 velocity factor), so I assume that the two adapters
are providing a conjugate match to each other. This confirms my
assumption that the insertion loss is due to reflections (impedance
mismatch), not absorption (true power loss).

Bottom line: UHF connectors work fine through the VHF range, and
are not too bad even on the 420 MHz band if you can stand about .1 dB
mismatch loss per connector.

By the way, I did not do the full 2-port calibration on the HP8753,
so there is a couple hundredth's dB ripple in the plots. I averaged
this out by eye to come up with the numbers in the above chart.

AL N1AL

P.S. Sorry, I guess I violated the Usenet rule against posting
objective data... :=)

# 1998. Re: Reflectors For H.F. use

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-07 21:08:37 UTC
From: Dave <noone@nowhere.com>
Message-ID: <beednYAFv4lGExPcRVn-iw@crocker.com>
Source record: 86893

if the surface is large enough and conductive enough then the incident waves
are reflected. note, this is a MUCH different effect than having several
near 1/2 wave resonant 'reflectors' on a yagi. creating such a surface
requires either a solid conductor like aluminum plate or a fine mesh where
the holes are much less than a wavelength in perimeter. so for 10m you
could get away with a course fence wire, but it has to be electrically
connected at all the joints like a welded 2x4 dog wire... then it has to be
several wavelengths on a side, lets say 3 for now, so about 90' by 90'...
then you have to shape it to focus the beam, a parabolic form is common but
it depends on the phase distribution of the feed system just what is
best.... so for the highest hf band you need a dish about 100' across,
bigger would be better. that is why dishes are used mostly for uhf and
above.

==========

What with his own government, most of the population and some prominent newspapers being against him, and several cabinet ministers having already resigned, its my guess puppy-dog Tony will resign before the next parliamentary election on the grounds of wanting to spend more time with his family. Otherwise there's always the remote possibility of him being found hanging upside down from a lamp post in Downing Street.

Having no constitution we do things more quietly, leisurely and maturely over here. We even managed to get rid of Mrs T who was in tears and without sympathy. But very rich of course.

As for little me, I was born stupid.

Exactly, Which is why there is so little information regarding 1/2 wave
resonant VS
smooth surface reflectors. Modeling shows that it is possibly worth while to
concentrate solely on reflector capture via multi elements as opposed to a
single reflector
and a long boom where as my previous investigation showed that combination
multi element
directors and reflectors showed little advancement. If the drive element is
multi banded then reflectors
would appear as full wave reflecters which would be an advantage.plus
providing the possible ability
for lesser beam width. I also have the feeling that grounding the highest
element will remove local
static effects. First examination shows that feed position is not as
critical as that required
for smooth dish forms

Source record: 86899

Unfortunate I have only a NEC 2 based program (Nittany Scientific's NEC-Win Pro), but with the Sommerfeld/Norton ground model you can approach the ground to within 1/1000 of a wavelength closely approximating the results of buried wires, and in very close agreement with your "RADIALS2" program. NEC programs do require a value for ground permittivity. NEC 4 based software is more expensive, being in the $800.00 range, plus a $500.00 license from the Lawrence Livermore Laboratory. In any case the data are easily compared with your program results.

I have measured my ground conductivity, but not yet attempted to measure the permittivity.

If anybody wants to get serious with antenna modeling I recommend Ansoft's HFSS (Often known as "Highly Frustrating Structure Simulator"). It costs a mere $30,000, with a $10,000 per year support payment.

Regards,

Frank

Cecil,

You appear to have some unique views of superposition and of standing waves.

In simple terms superposition says that one can combine two inputs, and the combined output is equal to the sum of the individual outputs. Not all systems exhibit superposition, of course, but I believe the elementary antennas considered here do indeed follow the principle of superposition with regard to current.

Why do you believe the "net" current somehow has different properties than simply the sum of the two component traveling current waves? You use the term "artifact", as if the net current is inconsequential or even incorrect. Does superposition break down? Distributed network vs. DC or AC model is not an issue, since the superposition must be performed independently at each point in the region of interest.

(You seem to like to use "net", but "total" or "algebraic sum" mean the same thing. I am not interested in any argument about performing the vector math correctly. That must be assumed.)

Standing waves are not static. The current may not "flow", whatever that means, but there is certainly real non-zero current at every point except the exact nodes of the standing wave. If you prefer, the standing wave current oscillates rather than flows, but that is of no special importance here.

Why do you believe standing waves are somehow inferior to traveling waves?

(This message is absolutely serious. No tricks or trolling. If you want to play word games, see ya later.)

73,
Gene

of course not, because you aren't reflecting. you are inducing currents in
the elements and those currents add up in the direction you want. if you
really want to investigate this you should get one of the good modelling
programs and try it out in various arrangements.

Note, multiple reflector yagis have been around for ages. there are some
good reasons why they aren't common on hf... first they are hard to build to
withstand weather. and second, the added performance on a relatively short
hf yagi is minimal. when you get into very long vhf and uhf yagis it is
more common to see multiple reflectors, but they are mostly used to
eliminate specific side lobes... and even then the only common designs i
remember have a total of 3 reflectors, one on axis of the boom and one on
each side. a similar effect can be done with the so called 'quagi' where
you have a loop element as the reflector and maybe as a driven element then

plane yagi type directors.

"Moron" vs. "Insane suicidal murderers" - not a good situation, I agree.
However, our only other option was a wimp.

>Don't you care what the rest of the world thinks of you?

Certainly I do. I want to be known as the country who helped to wipe out
the insane suicidal murderers.

>Don't you care what impact
>American foreign policy has on the rest of the planet?

Well... yes I do. If we could meet with more cooperation, there would be
much less destruction. This planet is running out of room for dictators.
The destruction in Iraq is being caused by power hungry idiots who think
they can become the next dictator - not by the US. We are attempting to
stabilize the country. We have attempted to help rebuild the country and
the insurgents have murdered the civilian contractors that were there to aid
the Iraqi people.

>Does Iraq look like a success
>to anyone?

Iraq never looked like a success - even when Saddam was in full power. Iraq
could have been a success - but it had a nutcase for a leader. Here you are
in the middle of the "black gold" center of the world and most everyone
still rides camels. That is why this crap happened to it. I have a lot of
hope for the Middle East. I suspect it will eventually rule the planet -
but certainly not with its present attitude - and certainly not without
being united by a common vote of the people.

>Doesn't it bother you that he's alienated every friend you have?

Bush is my buddy. We have the right friends. It was your choice to avoid
friendship.

>Prior to this, it was American policy and the American government that was
so universally
>hated around the world. Now it's going to be 'Americans' we hate.

Hate breeds war and more destruction. When will the folks of your persuasion realize that you need to stop hating? If you are an Iraqi - you should help us help you instead of fighting to support your hate. Look at Japan. A relatively small country that is a HUGE success. They smacked us. We had to smack them back. But we didn't leave them behind - and we won't leave Iraq behind. We all sincerely wish the fighting would stop, but it is clear that Iraq would remain unstable as ever if we just left. There are still way too many "would-be" dictators and nutcases.

>More sympathy
>for Bin Laden... More attacks on American institutions... More isolation. How blind
>can you dumb rednecks in middle-America be, not to see this?

More sympathy for an insane murderer who stirred up a massive wasp nest that stung everyone on the planet - including you? And you call *us* stupid? Bin Laden is the one who caused all of this! Bush HAD to make policies to stop this type of stuff. Your enemy *IS* Bin Laden and people like him - not the US. You can't see this?

>If you get hit again, or your economy goes into a deep depression, the American
>people will be getting exactly what they deserve!

You don't want that to happen. Believe me. You think it's bad now? Do what you can, on your side, to stop breeding hate - and the pyrotechnics will stop.

## 2008. Re: Fishing pole element construction facts

Newsgroup: rec.radio.amateur.antenna

They are really called "crappie poles" as they do not have any feed line loops. I will get an E mail for you tomorrow
Any fishing shop will have them if you refer to them as above which separates them from the more expensive "fishing blanks".Found out about all these things when I went to a major fishing show in Chicago where I spoke to all the reps.
You can get thicker wall types but I do not deem them as necessary but carbon type blanks (noodles) can be more useful at triple the cost if excessive bending is to be imposed for any reason but with the loss of stiffness. There is now available sticky back copper foil as hardware stores uprate their inventory for use on outside wood decks where before they used aluminum which is now prohibited for some reason with treated woods!

You can get them in 8,12,16 and 20 foot lengths and all parts have been interchangeable for me in that none fall out
as weight is applied such as ice. where extra tightening then occurs.Some suppliers up their prices to twice what
I have been able to buy them for.

Personally, I don't give a rats ass if you like the US or not. Funny, all
you fags hate us, but yet you come to US for financial aid at some point -
EVEN if you have money from oil. If ya don't like US, then quit trying to
get on our welfare roles. I'm sick and tired of all our tax dollars going to
you scum bags while our elderly and others go untouched with aid. You're all

a bunch of wimps. Our soldiers will do hand to hand combat with you any day of the week. Your people couldn't fart without holding a knife or gun. YOUR people couldn't hold anything over our guys in hand to hand combat. Hell - our female soldiers have more balls than you scum bags. US FOREVER - ALL ELSE (WHO HATES US) - DIE.

HeH. America in deep depression. And all those "rednecks" with a garage full
of nukes ---- 2nd Amendment approved and sanctioned nukes no less ----
and pocket rockets. Not to mention plain old ordinary "assault weapons".
Pissed off and armed to the teeth. And this limpdick, lowlife, pissant,
trolling Usenet with his message of hate? I wager he is the first one into
the hole. Trying to pull it in behind his sorry ass. Didn't he watch
O'sammy-ben-laden on Teee Veee the other day? Whimpering his message to GW
of "Please don't hurt me, I didn't -really- mean to knock the towers down.
I just wanted to fuck them up a little bit. I didn't know the USA still had
real teeth 'cause I was payin' attention to the limpdick left-liberal peace
freaks America's freedom of speech tolerates. Hell I thought America was
just like Saudi Arabia, the Sudan, and Afghanistan where subversive speech
gets your fucking head chopped off. I didn't realize that in America even
stupid people who have never had an original thought in their life are
allowed to speak as if they were the goddamn King of the World." Eh?

# 2011. Re: Reflectors For H.F. use

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-07 23:20:49 UTC
From: "aunwin@insightbb.com"
Message-ID: <l5yjd.311456$wV.72126@attbi_s54>
Source record: 86906

David,
The way all of this came about was that I modelled a 0,1wave length boom
with out restriction
to the number of elements used and without restriction regarding in-line
height.
It was then a surprise to me that where gain was the priority the NEC
program evolved a design with
multi reflectors in quasi parabolic form with parallel elements such as I
mixed up smooth dish
thoughts with standard antenna array thoughts. Thus my search for info and
outside thought.
Now if I placed a constant current COIL in the feed dipole responses would
over whelm me
and place me in a position of immobility (smile)
Regards
Art

There is also a reasonably good discussion in the ARRL Antenna Book. The
section on direction finding antennas discusses the directivity of shielded
loops vs loop antennas.

One has to be careful in distinguishing between small loop vs.
Electrostatically shielded ("magnetic") small loop antennas.
Small loop is typically less than 1/4 wave single loop made of tubing (low
resistance - losses) and with efficient matching network.
The shielded small loop is variation of small loop antennas using electrostatic
shield (tubing with gap - opening)

Above referenced sites seem to use the name Magnetic Loop for wrong antennas
(just simple loop).

Got that Reg, Tom, Dick and Harry?

Brian

I would recommend contacting K1RQG, who runs the 70cm and above EME net
on weekend mornings. He can point you at one or more people that
currently use state of the art dish feeds and preamp designs for 432Mhz
through 49Ghz moonbounce, and know the pitfalls plus the tricks to get
your best system receive performance.

Please respond to my address as shown, and I will send you his address
in an off newsgroup email. Joe doesn't need the spam that he might get
if I published his address here.

How about the only valid funtion of government is to protect the
rights of the individual citizens? For that, we need a police
force to protect us from criminals, armed forces to protect
us from foreign powers, and a court system to enforce the
laws. That's it, nothing else needed.

Thanks for the information Wes. I have only recently noticed the loading coil discussions going on, so guess I missed a lot of the earlier postings. Your curves are very similar to mine, although I plotted only those currents within the loading coil, that are spaced by the winding separation (Which happens to be the same as the overall segmentation). The far field is proportional to the portion of the current (within the helix) in the "z" direction, and assume that the x and y components are cancelled out. Such plotting seems to be supported by computing the integral of I(z)dz -- while realizing the limitation of such expressions.

I just tried to run your EZNEC files, but cannot since I only have the demo program. Will have to figure out a way to extract the NEC code.

The qsl.net site is incredibly slow, I had to make a couple of attempts to download your files.

Regards,

Frank

Because the net current is a *STANDING WAVE* made up of equal magnitudes
of current flowing in opposite directions. That makes the net current
zero, Gene. Standing wave current doesn't flow. The RMS value stands still.
Standing waves are only an artifact of the superposition process. Everything
that needs to be known involves the two traveling waves that cause the
standing wave. Asserting that standing waves flow into the bottom of a
loading coil and out the top shows a complete ignorance of how standing
wave antennas really work. After that false premise, none of the
associated conclusions are valid.

> Standing waves are not static.

The RMS value of a standing wave at any point is indeed static.

> means, but there is certainly real non-zero current at every point
> except the exact nodes of the standing wave. If you prefer, the standing
> wave current oscillates rather than flows, but that is of no special
> importance here.

It is of infinite importance. If the standing wave current oscillates in
place, it doesn't flow through the coil. W8JI says it flows into the bottom
of the coil and out the top. Nothing could be farther from the facts of physics.

> Why do you believe standing waves are somehow inferior to traveling waves?

Standing waves are an artifact of the superposition of two traveling waves.
Standing waves have a constant differing RMS value at every point on the
transmission line. Traveling waves travel and have the same RMS value all
up and down a lossless transmission line. What is it about that concept
that you don't understand?

Source record: 86772

Well, don't have access to that reference. I'm sure that it would clarify some
questions. Access to the once great Collins technical library is gone (sigh).

Built a couple models in MMANA. One for a shorted loop, and one for an
open loop. As expected, the shorted loop is vertically polarized, and the pattern
is in-line with the loop. [a magnetic flux pickup antenna].

Upon opening the loop, it forms a small dipole, with the two ends near each other.
It is horizontally polarized, and the directivity is perpendicular to the shorted loop.
[an electric field pickup antenna].

Of course it's hard to tell exactly the voltages that would produced by these two
different antennas, and how they would combine, magnitude wise. Rough order
of magnitude in MMANA is they are within a few dB for a diamond shape, 1m on
a side at 3.5 MHz. But this would depend on how well the magnetic coil coupled
to the dipole, and that's hard to tell in MMANA.

It would seem from this that the electrostatic shield does not necessarily help
things because it appears to degrade the directivity [assuming the magnitudes of the
two components are roughly similar ]. It would be interesting to see in real life if
the shield did degrade the nulls of the unshielded loop (accounting for the polarization
change).

Outch Yuri that is not very nice.!
The U.K. has a german lineage in the royal family and Germany certainly did not want
the U.K. and the Commonwealth to enter the war.( They begged otherwise)
I suppose that the U.S. could have asked us to join them in a resistance after Pearl Harbour
forced them into battle several years later but Russia would certainly not had the Russian
winter to back them up if they were not delayed by the Battle of Britain and possibly
finished up as the Worlds economic giant!
Do you think that the U.K. was silly to declare war alone on September 3 1939?
From a personal point of view my Dad would not have been boarding a boat for Dunkirk and
London would not have been subject to the Blitz and I would have known little of the trials of war
that awaited England's shores from a shore 21 miles away..
Would the UK have benefitted by waiting to the end of '42 for a request by the U.S. or, to the point.
how should the U.K have handled things if they had the benefit of your own personal wisdom and fighting career
and battle experiences?
Nothing personal but I am very proud of that centuries old saying that
" In the corner of every battle field there lies a piece of England" which is justly earned
and you just waving a flag of your new country does not release one from the follies of the past.
Yuri, you are out of your league in your personal insults whether it be to an individual or a Country
I am proud to be but a small piece of England and to have worn a British soldiers uniform even tho
I now live with my American cousins.
Art Unwin KB9MZ.....XG.

# 2030. Re: Loop antenna electrostatic shields

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-08 04:56:18 UTC
From: Tom <noname@noprovider.nodomain>
Message-ID: <S%Cjd.3153$rx5.2079@trnddc06>
Source record: 86776

Managed to model the shielded loop in MMANA. Single turn loop, with
one nearby wire as shield, and two nearby wires as shield. Set the spacing
of the wires 10mm and 5mm away from the loop, didn't make any difference
in results. [using 0.8mm wires].

The single shield wire improved the E-field rejection a little bit (maybe 3
db)
over the unshielded loop. Two shield wires degraded the E-field rejection as
compared to the single shield, but still a tiny bit better than the
unshielded loop
(maybe 1 dB better).

Pretty much the shield provides very little E-field coupling compared to the
H-field response of the loop.

So I'll retract my initial statement.

Hopefully, we can lay this thing to rest soon. The forward current
flows into the bottom of the coil and out the top. The reflected
current flows into the top of the coil and out the bottom. Those
two currents are very close to being equal magnitudes but their
phases are rotating in opposite directions. That is not a job
for the lumped circuit model. That's a job for the distributed
network model, something that you guys seem to have first ignored
and later tried to sweep under the rug.

Yah, but with something like 43,000 automobile deaths (cars die too,
mine did right in the driveway this morning) and no one gets excited,
why get concerned about 15,000. We need to outlaw cars first.

Actually accidental deaths by guns is its lowest since 1907 and
violent crime is at its lowest in 20 years even with the economy
suffering a tad.

While the rest of the world is seeing strong increases we are seeing
decreases in violent crime. In addition, every state that has passed
"right to carry" laws, firearms crimes have gone down.

Contrary to popular belief outside the US we are just normal people
and it's not at all like the old "Wild West". OTOH a high percentage
of the population does own firearms.

Now, I gotta go clean my AK-47. Deer season is opening soon.

Unless of course worrying is a hobby 8-}

In my estimation, from HF to 70 cm what is more important than
connector type is that the connector is properly installed. Which
means proper cable dressing, effective soldering to the connector and
then adequate weatherproofing once connected to the antenna.

I made a "utility antenna for my 26 foot coast-wise sailor, just a folded dipole with a PVC pipe 'X' to support the twin lead. You can size the PVC to suit the size of the dipole. It worked okay, nothing special though. Another version made in the same manner is a 10 meter transmitting antenna and it also is a reasonable compromise. Getting it up as high as possible seems to help too. I use a 'Mast staff' and hoist it to above the mast head in use.

you must watch out when telling any of those automatic optimizing programs
to maximize or minimize any one value without limits. it is very possible
to get super gain antennas that can't be physically built because of either
construction problems or things like extremely low feedpoint impedance.
most of the time you end up needing to build them from superconductors to
keep feedpoint losses down. or you need an extremely good insulators to
keep high voltages on elements that are almost touching from arcing.

## 2043. Is it worth it? Will I notice?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-08 13:56:46 UTC
From: Ken Bessler <kg0wx@NOSPAMyahoo.com>
Message-ID: <lWKjd.75151$%x.68322@okepread04>
Source record: 86789

OK, after the thread on PL-259 losses, I figured
my system (ant gain - connector losses - coax loss)

150 mhz total net gain 1.006 DBi
450 mhz total net gain 2.797 DBi
Antenna tip is 32'6" above ground

My proposed system would replace the RG 58 coax pieces
with a single section of Flexi 4XL and the antenna would
be a Comet GP-9. The new figures are:

150 mhz total net gain 7.919 DBi
450 mhz total net gain 10.553 DBi
Antenna tip is 47'6" above ground

150 mhz = 6.913 db improvement
450 mhz = 7.756 db improvement
Antenna tip 15 feet higher

Cost - about $250 for the improvement.

Now here's my question - will I notice the improvement
enough? I've had several OM's tell me that on SSB, CW
or HF I would but not on 2m/440 simplex and repeaters.

I'm glad to see objective data. But as I've said before, it's not terribly relevant to typical ham radio antenna applications. It would be very interesting if you would build a simple L matching network with as low loss as possible (to mimic a ham installation) and repeat the measurements, readjusting the matching network for each frequency and connector to minimize the insertion loss. Then you'd be eliminating mismatch loss from the measurement, and we'd see only the connector (and matching network) dissipative loss. That's the only loss of concern in an antenna system presuming you have a way to adjust the match.

Well, a 6 dB boost would double your range, IF you aren't hitting the limits imposed by your radio horizon. VHF and UHF don't "bend" much, so once you go beyond your radio horizon, you're pretty much done, no matter how much signal you had. It will improve your signal into repeaters, where you were a little noisy before, you should be quiet. On simplex, you'll notice better signal once you get far enough away that you used to be no longer full quieting.

In an FM receiver, there is a signal limiter, that caps the signal level, so if you were already "full quieting", then no amount of power increase would result in a better signal. If you are far enough away that you're not full quieting, then yes 6dB will be noticeable.

I have a couple of GP-9s and can tell you the gain figures are a bit inflated and not referenced to anything. A dipole array with optimum spacing between dipoles is about the most gain for size that I have encountered in VHF/UHF antennas. For VHF, a four bay dipole array at 20ft in length has 6dBD gain omni and the GP-9 claims 8.5dB(?) from three 5/8 elements. On UHF, a 16 element dipole array has about 9.8dBD gain and the GP-9 claims 11.9dB(?) for eight 5/8 elements. Something looks fishy to me.

Gene, W4SZ wrote:
"Standing waves are not static."

Incredible!

My "American College dictionary" defines "standing wave": "a distribution of wave displacements , such that the distribution in space is periodic, with fixed maximum and minimum points, with the maxima occuring everywhere at the same time, as in vibration of strings, electric potentials, acoustic pressures, etc."

Note the word "fixed" in the definition. That`s a synonym for "static".

For how this applies to antennas and transmission lines, see page 177 of Kraus` "Antennas", third edition, Figure 6-7. Notice that current reverses 1/2-wavelength back from the antenna`s open-circuit endjust as it does in the case of the open-circuit transmission-line, as shown by Terman on page 92 of "Electronic and Radio Engineering", 1955 edition, and on page 94 in FiG. 4-5 (a). This all starts at the reflection point and progresses the same regardless of the length of the antenna or transmission-line. It is due to superposition of the forward and reflected waves, just as Cecil maintains.

Advice: Never argue with Kraus and Terman.

Best regards, Richard Harrison, KB5WZI

The figures speak for themselves. If you are doing any VHF/UHF weak signal work, regardless of mode, it WILL be noticeable. Depending on the distance of the sending station or repeater, it can even be noticeable on FM.

Nothing can distpute your math - something's up.

I've changed plans a bit, though - the Boeing ARC 2 meter
repeater is only 4,000 feet away and I'm worried about
intermod. So, instead of a high gain antenna at 20', I'm going
to go with a moderate gain antenna 10' higher. The idea is
to get good gain with a farther horizon rather than high gain
with a closer horizon.

Plus, it's cheaper, too!

Instead of the GP-9 @ 20', I'm going to add a 10' mast
and go with a GP-3. Installation sould be a lot easier, too.
Now, though, my gain figures are 2.913 db improvement
on VHF and 3.056 db improvement on UHF.

I'm seriously starting to wonder if I should just leave well
enough alone - the MFJ-1729 is performing well. I was
talking to N0IDW on the 145.19 Winfield, KS machine
(a distance of 32 miles) and I could hit the reverse button
and hear him on the input. He, however, could not hear me
on the input.

# 2052. Re: Loop antenna electrostatic shields

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-08 17:58:10 UTC
From: Joel Kolstad <JKolstad71HatesSpam@Yahoo.Com>
Message-ID: <M-qdnYFgX72hLhLcRVn-iQ@comcast.com>
Source record: 86798

Thanks for the information, everyone. I'll read up on a few of the references. I have found a few web pages that compare the sensitivity of the shielded vs. unshielded loops, and the shielded loop always ends up with slightly less sensitivity.

Could anyone answer the following question? I'm trying to make things simpler here than what happens what a real antenna: Let me take an ideal circular conductor, say, a meter in circumference. Next I'll stick it inside a perfectly conducting loop of pipe (the shield) that has an infinitesimally small slit in it to prevent creating a shorted turn. Finally I'll create a magnetic field at a very low frequency (say, 1Hz -- so that the loop is clearly electrically small) and insert the loop into it such that coupling is maximized.

Question: Will the current on the inner conductor be identical to the case where there is no shield? Is there any current on the shield? Does anything change if I ground the shield?

Hmm... I'm thinking I should move this over to the electromagnetics newsgroup!

The "shield" is actually the antenna, and the gap in the "shield" is
the feedpoint of that antenna. You will do well to make the "shield"
out of a good conductor, and to get the benefits of rejecting
vertically-polarized electric fields generated nearby, you should make
the antenna very symmetrical. See the discussion in King, Mimno and
Wing's "Transmission Lines, Antennas and Waveguides." I think I have
a .pdf file of the relevant section somewhere. I particularly like
that one for its qualitative explanation, clearly presented. I've
seen other decent explanations in places like Johnson and Jasik's
antenna book. The explanations in such texts that I've seen all
agree.

A key advantage of the "shield" is that it simplifies the task of
making the antenna symmetrical, though I've seen a lot of old ARRL
pubs that completely miss that point. If you realize that that's what
you're trying to accomplish in the "shielded" construction, you'll
find you can do quite well with a multi-turn "unshielded" loop, too.

Cheers,
Tom (one with a last name)

Hi Tom,

Those are some good additional references; thanks. I was surprised to find that Kraus' antenna book doesn't discuss shielded loops (well, the most recent/last edition -- I've heard that some material from earlier editions has been pulled from it). Your explanation matches the 'other Tom's' explanation, and sounds plausible to me, yet there are others posting here who seem to disagree. The fact that you have several more theory oriented books agreeing lends a lot of support to it.

If you do find a PDF version of the section of the King/Mimno/Wings book, I'd love to get a copy.

That was meant to setup the problem such that the loops is electrically small and such that only quasi-magnetostatic analysis would be necessary. In actuality I'm thinking more along the lines of WWVB loop antennas -- 60kHz.

> Why bother with the complication of shielding?

The idea is that there's a lot of predominently electric field interference around (60Hz power lines, for ones) and that the shield -- if grounded -- can short out that component of the field and get the loop to respond primarily to the magnetic field.

Everything is relative.

As Dee said, if you do weak signal work you will notice it.

If you figure investment Vs performance yours is ahead of mine
http://www.rogerhalstead.com/ham_files/tower.htm in both dollars per
watt and hours to install. Took me two years to install, but I do put
it to use. OTOH I've thought of replacing the UHF/VHF arrays with a
single Diamond dual band repeater antenna, EXCEPT for the lightening
problem.
That tower has been taking about 3 hits a year and I have one Diamond
repeater antenna in the shop that looks like a well used exploding
cigar. The top end is pretty frazzled and the matching network in the
base is shorted. Inside it vaporized the top 4 or 5 inches of the end
element.

In my opinion the height is the important element, but I'd not worry
about the extra gain of the antenna. OTOH you *might* receive some
intermod, but you *probably* won't. (note weasel words)

Hi Tom (WALN),

I thought the original question related to whether or not the magnetic
field penetrates the "shield".

I have a problem calling the shield the antenna because I have built loops
(144 & 440 MHz) which do not have this classic form of shield, but a
unidirectional screen, and good nulls off both sides. I made the shield
from a series of vertical wires connected to a conducting strip only at the
bottom.
I also wonder about the symmetrical concept as a standard "Hazeltine"
loop had the opening of the shield at one end near the bottom, near the
feed.
I suspect that a symmetrically constructed loop will have less
electrostatic response, however. This seems to make sense. Then there is
the matter of the practicality of construction. If it is easier to make the
loop unsymmetrical and shielded, then that's ok.

73, also with a last name,

The French wine industry was decimated in the 19th century by
a phylloxera infestation from America. The problem was solved by
using native American root stock onto which French grape vines were
grafted. Most wine grapes in America have European ancestry.
I doubt whether there's a grape vine in the world that cares
who is president of the U.S.

>Ken KG0WX

Well, Ken maybe your "OM's" didn't eat their Wheaties. A 6dB improvement means you have quadrupled your ERP over your existing system. You have also increased the distance to your radio horizon with the increse in antenna height.

Why they would say you won't notice an improvement is beyond me. In plane language here are a few things just a 6dB improvement mean. You can reduce your radios Tx power by a factor of 4 and have the equivalent ERP, 6dB doubles your range Tx and Rx (within the limits of your stations LOS - line of sight). Stations that were noisy will now be full quieting, be it simplex or repeaters you work.

In even simpler terms, "night and day".

What are you waiting for?

I think I understand what you both are saying. In the case of a
standing wave, the 'current drop' Cecil refers to (as I understand it)
is simply the current differential between two positions
Iz2 - Iz1, where I(z)=Imax(cos(wt + phi(z)), the amplitude of the
standing wave current as a function of position z. Phi being the kind
of phase which for a traveling wave varies with time at a given point,
and in this case varies with position along the standing wave. The
distinction being that Phi is not the phase of current with respect to
voltage.

The other point of disconnect between the parties hereabouts relates to
the occasional lack of distinction between the 'flow' of electrons, and
the propagational 'flow' of an EM wave.

Here's more what I had in mind. In a source/transmission line/
load configuration, where the loss in the transmission line is 3dB,
the load voltage and load current decrease by the same percentage.
Saying that the voltage wave dropped but the current wave didn't
drop seems a little strange to me. Also, saying the current wave
flowed but the voltage wave didn't, seems a little strange.

The signal attenuated by the transmission line has the identical
equations for voltage and current except for the 'Z0' constant. Does
that Z0 term have the power to cause the current wave to flow and
the voltage wave not to flow? Does the current wave leave the
voltage wave behind in the transmission line dust? Since RF waves
always move at the speed of light, exactly where does the voltage
wave reside when it is not moving at the speed of light and how does
it magically arrive at the load at the same time as the current wave
if it doesn't flow at the speed of light along with the current wave?
(For the humor impaired, this is pure unadulterated humor.)

Doesn't "drop" and "decrease" mean the same thing? Webster's says
they are synonyms. How can a voltage wave drop in magnitude but a
current wave cannot drop in magnitude even if it is defined as
having a constant relationship (Z0) to the voltage wave?

Doesn't "flow" and "travel" mean the same thing? How does the
voltage traveling wave get to the load without flowing? Seems if
the voltage traveling wave didn't flow along with the current
traveling wave, it would never get to the load. But, they tell me
that logic doesn't matter anymore and quantum physics rules. There's
no such thing as reflected energy anymore and only a mush of energy
ever exists. Never mind the ghosting on your TV. That is all in your
mind. Oh yeah, ghosting TV's never reach steady-state. Never mind that
radar couldn't work without reflected energy. Oh yeah, radar never
achieves steady-state. Now I understand completely!

>> In the classical electromagnetic model, E & H are completely
>> separable.

I got to wondering exactly how Bart goes about separating the E-field from H-field in the light from the Sun before it gets to Earth. :-) But I'm only a lowly grasshopper, trying to grok the deep thoughts of the gurus. (As always, in good humor)

Hi Joel,

When I was calibrating my Atomic Clock, years distant, my antenna was
a simple 20' whip above the fantail of my ship. We used WWVB and an
unique modulation envelope to perform the job. This didn't make the
antenna particularly efficient, but it was suitably sensitive. Still
and all, there are roughly 5 orders of magnitude down to the 1Hz
region.

You may as well use WWVB as your testbed, or one of the submarine
fleet frequencies around 12KHz. One station is nearby here at Jim
Creek. They use a T antenna of about 1000' tall with a top hat of 6
cables strung between two mountain tops (about 4000 to 6000 feet
between them). The numbers may be off, but you can judge that the
scale is impressive (quite a sight).

1Hz noise field would come from meteors striking, and ionizing the
upper atmosphere. I doubt you could judge against any local sources
of noise compared to that chatter. Given that line frequency would be
6 Octaves away, if you tuned your antenna (it would be tuned, wouldn't
it?), you would have to be next to a noisy power plant to hear it.

Question is: Why do you promote W8JI's stuff when it is quite obvious
that he is NOT familiar with standing waves. If he were familiar with
standing waves, he wouldn't be asserting that net standing wave current
flows into the bottom of the loading coil and out the top of the loading
coil. Are you absolutely sure that you want to promote the alleged
"information" on W8JI's web page as absolute fact? If he is so right
and so capable of defending his assertions, why isn't he here right
now? (Trying to get W8JI to follow me down the Primrose Path :-) as
he did when he asserted that "differential" effects are "completely
unrelated" to "common mode" effects.)

# 2069. EM field og GSM and microwave oven in V/m ?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-08 23:31:43 UTC
From: Thierry <->
Message-ID: <419001ed$1@news.vo.lu>
Source record: 86815

Hi,

I haven't find a better ham newsgroup for this question... so sorry if it is
s bit off subject.

I read somewhere that a GSM 900 MHz produced at electromagentic field of
50V/m (!!) placed at the ear, a 900/1800 Mhe up to 70V/m and a microwave
oven working at 2450 Mhz (>850W) up to 80 V/m on top the cabinet.

These values are falses !
If we convert these data in watts, we see that the power radiated is greater
that the emitter power. Hi !!

More than 100 GSM were recently tested in Belgium by labs and controlled by
the P&T (IBPT) and confirm that the measured fields, at one or two
exceptions, are BELOW 1V/m.
We are thus well below the energy released by any ham device.

Problem I don't know if the microwave oven value is correct.
Can someone know its EM field expressed in V/m ?

Thanks in advance

Thierry, ON4SKY

So does a current wave flow or not? This is not a trivial question
and tends to distinguish between the problems one can solve with
a DC circuit model Vs the more complicated distributed network model
where current waves and voltage waves share a lot of common characteristics.

Source record: 86818

The NTIA measured a series of microwave ovens as part of interference
testing for 802.11.

Here's a link to the main page
http://www.its.bldrdoc.gov/pub/ntia-rpt/94-303-1/

And a link to the measurement results
http://www.its.bldrdoc.gov/pub/ntia-rpt/94-303-1/chap5.pdf

Summary of the summary:

Worst-case emissions were near 2450 MHz. Ovens averaged about
+113 dBuV/m, the worst case one was about +128 dBuV/m measured at 3
meters.

dBuV/m is dB relative to a microvolt per meter.

Hopefully I'm not hosed up here, I think +120 dBuV/m is the same as 1 v/m.

That would make these ovens E-fields about -7 dBv/m to +8 dBv/m, or about
0.45 v/m (mean) up to about 2.5 v/m worst case).

Don't change the antenna but go for height and a good grade of coax. It
won't show up for about 50 feet or so of coax on 2 meters but if going to
100 feet of coax it will on 440.
If your setup is doing what you want it to put the money to something else.
I don't do too much with the repeaters and FM so I was just using some rg-59
(75 ohm coax) to a home made dipole about 20 feet up the tower. It does
what I want it to on FM. Unless it was to add some tower I would not spend
$ 250 for an FM antenna system just to work repeaters.

# 2075. DOUBLE RESONANCE IN DIPOLE...THE CAUSE?????

Newsgroup: rec.radio.amateur.antenna

Source record: 86821

Hi,

I recently tuned up a VHF dipole, and i got
a double-dip, double resonance for the swr, and
also the minimum swr was around 1.3:1

I did some modifications, and the double
resonance was was gone, plus the swr was down
to less than 1.1:1

I'm certain that one of two things (or a
combo of both) did the trick, but i wanted to
see if any of you seasoned antenna boys could
guess what the problem was.

Thanks for your input!

Slick

Well, I've read that down around 60kHz there's plenty of interference due to noise on the power lines (I doubt harmonics, probably just plain old noise from, e.g., switching power supplies). But in any case, I'm at the point where I need to just build something and see how it performs.

Actually, there is quite a lot of fun to be had working FM simplex
and repeaters here when the band opens up. One minute you're
rag chewing with the locals on 146.490 simplex & the next thing
you know someone checks into the group from 3 states away!

That's when it's time to switch over to the beam and the Elecraft.

A few years ago I was living on a hill. With a 14 element yagi on
a 35' mast, I could just hear the Tulsa 145.110 machine when the
band started to open. Then it'd open up 100% and I'd talk to south
Texas on 2m FM or 450 miles away on 446.000 simplex.

Neat!

Tom Bruhns, K7ITM wrote:
"See the discussion in King, Mimno, and Wing`s "Transmission Lines, Antennas. and Wave Guides"."

Ronold W.P. King did a fine job explaining "closed circuits as antennas". It starts on page 224. The shielded loop is diagrammed on page 234.

As Tom Bruhns says, the exterior of the loop is driven from the gap at the midpoint in its shield.
The shielded wire loop is coupled by its proximity to the interior surface of the shield. The outside of the loop is coupled by conduction across the open circuit edges to the inside surface of the loop. The gap is the drivepoint. The secret to noise immunity is symmetry and balance in all aspects of the loop.

Best regards, Richard Harrison, KB5WZI

That setup is a big differance than in your first posting. I mentioned I do not do much FM work on 2 meters . I do work weak signal on 2 meter and 432 mhz ssb. It is not too unusual to work long distances that way. Ham radio has many things that can be fun. I usually think of the repeaters and FM as local contacts. I have worked from North Carolina to Canada about twice on 2 meter FM. Using a good antenna and ssb it is common to work out to 200 to 300 miles. The band "opens" a lot more if you have the advantage of about 10 to 20 more db of ssb.

If it has two elements (sure, verticals can have two elements)
then a difference in resonance between the two elements could
easily have been the cause.

Good luck following the weak signal VHF/UHF track here. 10 meters is
short for this bunch, except for very few. Less than half dozen appear
to know what EME is.

Art Unwin wrote:
"The U.K. has a German lineage in the royal family and Germany certainly did not want the commonwealth to enter the war."

More than German lineage. All the major caesars of europe at the start of WW-1 were Victoria`s grandchildren. Hope Art is recovering well and rapidly without complications! George the 5th offered the Tsar of Russia asylum along with his family, at the time of the revolution, but it was too little and too late and they were all murdered.

Germany was insulted and felt abused by terms of the WW-1 treaty imposed on them at the end of the war. Germany deserved harsh restrictions. The Tsar, The Kaiser, and George 5th were all cousins.

After Serbs assassinated an archduke in Sarajevo, the Tsar felt obliged to avenge his fellow slav. He would invade. It was August and holiday month in Europe. No one should take notice or retaliate. Wrong!

The Kaiser felt threatened and retaliated. So, by accident and error, a war erupted from a family row.

Hitler was an ambitious WW-1 veteran who promised renewed prosperity in the middle of a world-wide economic depression, and reclaimed glory for Germans. He had no scruples regarding ascension to Fuhrer, but his personal habits were good. He didn`t regularly smoke, drink, chase wild women, or eat meat. He was persuasive as a speaker and promised to right the wrongs imposed on Germany. Also, the Bolsheviks were a real threat to the whole world, and Hitler was anti-Bolshevik!

Hitler delivered on prosperity and "living room" for Germans until he overextended into Russia. He micromanaged his generals who were actually often good at waging war. As a former corporal, Hitler was inspired but outclassed and doomed by the size of the war he had undertaken. He had many fantastic new weapons, but made the mistake of ridding Germany of Jews before they could make an atom bomb for him.

Art asked:
"Do you think the U.K. was silly to declare war alone on September 3, 1939?" No. Hitler had to be stopped. It should have come before Munich. It should have come when Hitler disregarded the restrictions on German rearmarment. It was already too late at Munich. But the League of Nations had been rejected and allies were very hard to find early on. No one can know what would have played out had history had taken a different turn at some point. Maybe after Poland, Hitler would have gone after Russia. There was a score to settle there from WW-1 and Hitler had the Bolsheviks on his list of those to subdue. The WW-1 allies could

have furnished Russia and Germany just enough weapons to completely exhaust each other.

We don`t learn quickly. do we? Why didn`t we do that with Iran and Iraq? Oh, that`s complicated by their oil production which the world can`t afford to lose.

Best regards, Richard Harrison, KB5WZI

Art Unwin wrote:
"The U.K. has a German lineage in the royal family and Germany certainly did not want the commonwealth to enter the war."

More than German lineage. All the major caesars of europe at the start of WW-1 were Victoria`s grandchildren. Hope Art is recovering well and rapidly without complications! George the 5th offered the Tsar of Russia asylum along with his family, at the time of the revolution, but it was too little and too late and they were all murdered.

Germany was insulted and felt abused by terms of the WW-1 treaty imposed on them at the end of the war. Germany deserved harsh restrictions. The Tsar, The Kaiser, and George 5th were all cousins.

After Serbs assassinated an archduke in Sarajevo, the Tsar felt obliged to avenge his fellow slav. He would invade. It was August and holiday month in Europe. No one should take notice or retaliate. Wrong!

The Kaiser felt threatened and retaliated. So, by accident and error, a war erupted from a family row.

Hitler was an ambitious WW-1 veteran who promised renewed prosperity in the middle of a world-wide economic depression, and reclaimed glory for Germans. He had no scruples regarding ascension to Fuhrer, but his personal habits were good. He didn`t regularly smoke, drink, chase wild women, or eat meat. > The secret to noise immunity is symmetry and balance
> in all aspects of the loop.

Exactly. But to me, there is no such thing as noise immunity as far as far field noise. The only noise that really can be reduced, is any possible common mode related noise due to lack of a balun device, whatever, at the feedpoint. And that assumes you actually have shack noise to reduce. Not all do. IE: using a loop out in the middle of the woods with a battery radio, etc...You can change polarity to reduce maybe 20 db or so, but thats another issue...As far as far field noise, the only way to reduce, is to ensure better balance. Better balance gives you deeper nulls, and hence, lower noise, IF!, you are using the loop to *NULL* the noise source. If you don't turn the loop to null the noise source, it will be just as noisy as any other loop. But as mentioned, this good balance can be attained with unshielded loops also. As far as I can tell, and I have tested this in the real world, balance is what separates a good loop from a medeocre loop. Not a shield, etc.
The split shield is just one method used to provide good balance. Thats why they are often used for DFing. With good balance, the nulls will be sharp, and there will be little skewing of the pattern. None of the shielded loops I've tried were any quieter to far field noise than my unshielded loops. Other than small differences in signal strength due to size, turns differences, the overall s/n ratio was the same. I could not hear anything on one loop, that couldn't be heard on another due to any increase or decrease in s/n ratio. In other words, all my loops act pretty much the same, shielded, or unshielded. Yes. I made a few comparisons long ago, shortly after you introduced
your program, and found major disagreement. NEC-4 approximately agrees
with the measurements made long ago by Brown, Lewis, and Epstein (whom I
know you've never heard of), once you make reasonable assumptions of
ground conductivity and dielectric constant. Your program gives very
different answers. At the time, I concluded that there's considerable
coupling between radials, which your program doesn't seem to account
for. Interested readers should look in the google archives for postings
in this group on the thread "Ground Radials" in July 1998 and
"Evaluation of G4FGQ Freeware Antenna Software" in September 1998.

>
> But in view of the large uncertainties involving ground conditions, accuracy
> is not worth making much of a song and dance about.

True, but in the past, you've used the results from your program to
reach conclusions about radial systems that I didn't, and don't, believe
to be valid. (See the threads mentioned above.) I don't think it's wise
to draw conclusions from a program that gives results which are
demonstrably very different from the only measurements regarded to be
reasonably well made.

Let's not call it "relative gain". There's no need to invent new nomenclature to describe known quantities which we don't understand. There are plenty of terms which are universally agreed upon and hence communicate concepts adequately -- inventing new ones just obscures what we have to say.

An "external load" (by which I believe you mean a receive antenna) is necessary for measurements, but not for calculation as by a program. But there's no harm in using one for computer analysis, as long as you don't misinterpret what the results mean.

>
> The gain evidenced in this remote antenna is not some arbitrary change

I believe you mean the *signal strength detected by* rather than *gain evidenced in*. If you make that replacement, I agree. Otherwise, it makes no sense -- the remote antenna does not "evidence gain".

It encompasses differences that exceed 1dB,

I'm having some trouble understanding this, too, but think maybe you're trying to say that hams want to maximize the signal received by a distant station. If so, I agree. But your analysis doesn't show how this is done by increasing Rr. As I said earlier, the advantage to raising Rr is to improve efficiency -- your models were nearly 100% efficient, so weren't able to demonstrate this. If you had added resistance to simulate ground resistance as I had suggested, this would lower the efficiency so the effect of changing Rr could be clearly shown. And raising the efficiency does indeed improve the strength of the received signal.

Again, I'm baffled. I'm sure that more highly educated readers than I understand what you're saying, but I also hope that even those with less education in the fine arts of language can understand what I've said. The principles involved are really simple, and I hate to seem them made unnecessarily complex by misinterpretation.

## 2093. Announcing SmartSmith version 1.5.3

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-09 14:07:58 UTC
From: w9dmk@crosslink.net
Message-ID: <4190cb2a.2581031@news.crosslink.net>
Source record: 86842

SmartSmith version 1.5.3 - now available at
http://www.qsl.net/w9dmk

This release incorporates the following major changes:

Main Window -
The main window has been shrunk to fit comfortably in an 800 x 600 display environment. The earlier releases were all designed for a 1024 x 768 (XGA) display environment, and users with older systems had great difficulty in using the system on an 800 x 600 (SVGA) display. In order to accomplish the re-sizing of the main window, the Smith Chart display was reduced in size to 85% of its former size. The 9 different matching section controls were also removed from the main window and given their own modal dialogue boxes that are exclusively selected and shown floating above the main window only when in use.

Range of Control over Elements -
All matching section controls other than those involving lengths of transmission line were extensively revised to provide the user with a greater range of values. In this release, each control has a range of 5 decades and 50 discrete values within each decade. For example, the Series Resistance matching section now starts at the value 0.1 ohm and extends to a maximum value of 10000 ohms in 250 steps. Likewise, the series capacitive reactance matching section starts at a value of 0.1 ohms and goes to a maximum value of 10000 ohms of capacitive reactance, regardless of frequency. Each matching section control displays its current setting both in ohms or milli-Siemens, as appropriate, and in component values, such as microHenrys or picoFarads. The exception is Series Resistance, which displays only in ohms. Each control also displays its "dial" or "counter" setting between 0 and 250.

The matching sections that employ transmission lines (Stub Open, Stub Shorted, and Series Transmission Line) still display their value in electrical degrees and in meters, as in previous releases. However, note that only "Stub Open" and Serial Transmission Line display their electrical length in degrees directly in the spin control display, whereas the "Stub Shorted" displays its electrical degrees below the spin control display along with the length in meters. This peculiarity in "Stub Shorted" is in order to make "Stub Shorted" behave the same as all other controls. Each of the other controls starts with a value that has the least effect on the existing impedance situation spins upwards to a value that has the greatest effect. In order to accomplish that with a shorted stub, it is necessary to start the shorted stub at its maximum (90 degrees) length and spin it up to its

shortest length (0 degrees).

Help File Improvements -
The Help File now includes topics on "Designing Pi Sections" and "Quick Start". The "Quick Start" topic goes through a simple design of an L-Section to match a high impedance, complex load to a 50 ohm source. It also goes through a more difficult design using a series transmission line section to create a match with a high impedance, complex load and a 300 ohm line. The latter exercise is take directly from Chapter 28 of the ARRL Antenna Book, 17th Edition.

Tnx and 73,

Bob, W9DMK, Dahlgren, VA

Rig up a random length insulated wire temporary antenna outside to a tree or
something. Bring the end to your receiver and wind it around the outside of
the radio case a few times and temporarily connect the free end to something
grounded such as the ground pin of a duplex outlet; be careful! This may
give you some capacitive and inductive coupling especially if your radio has
a ferrite rod antenna. It may, on some bands, give an improvement.
Experiment a bit. Have even wound the telephone cord around a portable. Also
connected capacitively from the whip of a DX394 to a plastic covered metal
clothes line and right now I've got a lead from the receiver whip clipped to
a six foot metal bedroom curtain rod! It even improved very weak reception

here from European Long Wave stations on 152 to 198 kilohertz. Yup that's around a wavelength of 1500 metres! Also if you've got a phone with any metal in it (most phones nowadays are plastic!) clip a lead from your whip to that. Try anything that might work and is safe.
Have fun. Terry.

## 2095. Re: Is it worth it? Will I notice?

Source record: 86840

> Well, a 6 dB boost would double your range, IF you aren't
> hitting the limits imposed by your radio horizon.

---

Clarification: the coverage AREA doubles for the above situation, but the "range," or distance from the transmit antenna to a given field strength value increases only by about 40%.

Here are the numbers, using the FCC's F50,50 curves for UHF NTSC TV propagation.

50W ERP from 100 feet above average terrain:

60dBuV/m at 2.99 miles
Coverage area within the 60dBuV/m contour = 28 sq miles

200W ERP from 100 feet above average terrain (a 6dB ERP increase from the above example):

66dBuV/m at 2.99 miles
60dBuV/m at 4.2 miles
Coverage area within the 60dBuV/m contour = 55.4 sq miles

The radio horizon for these examples is located about 14 miles from the antenna site (at a 0.15 degree depression angle).

Dipoles are essentially harmonic devices, so they experience harmonic resonances.

If you find resonances that are not harmonic on a dipole, then there are loading objects that are producing them.

What exactly is your dipole? What is in proximity to it? How do you know that the coax is choked properly?

At what two frequencies? What construction, feed type...? What method
of measurement and equipment type/numbers?

First, let's determine if there even is a problem with the antenna...

>
> I did some modifications, and the double

> > Note the word "fixed" in the definition. That`s a synonym for "static".

This is arguable, but only at the nit level. Synonyms don't always fit
exactly and it depends upon how they appear in the sentence.
The passage says "...fixed maximum and minimum points...". This is
"FIXED...POINTS" of the standing wave. The maximum and minimum *points*
remain in the same location. Indeed we can also se the word static to
describe these *points*.
HOWEVER, the voltage at any one (non zero) point is not static as it
varies at the RF rate. I believe one poster used the phrase "a standing
wave is/is not static". Using the phrase "a standing wave is static"
implies meaning of the second type. That is, that the whole phenomenom is
static, which is is not.

So there! Play with words if U like. How about discussing the concepts...

Roy, W7EL wrote:
"The principles involved are really simple and I hate to see them made unecessarily complex by misinterpretation."

Amen.

Directive gain according to Terman is distribution in space of radiated power versus the power that would be radiated by an isotropic. Losses are not considered.

Power gain takes loss into account and is the ratio of the power necessary to an isotropic versus the power to a gain antenna required for the same signal strength in the same direction.

Kraus says the directive gain is the ratio of maximum power density to its average value over a sphere as observed in the far field.

Terman and Kraus agree in their calculated examples. The directive gain of an elementary dipole (Kraus says maybe i/10-wavelength) is 1.5. It can be found on page 34 of Kraus` 3rd edition. It`s the same on page 871 of Terman`s 1955 edition.

The directive gain of a 1/2-wavelength dipole is 1.64 for Terman. For Kraus, it`s 1.63 on page 35. These are power ratios, not dB.

Irv,
I have not been able to dig around yet for my source that was in Missouri
I did however look at E bay and there was one supplier SHALLOR I believe the
name was
that was selling the exact type I was talking about and in a similar price
range
I did send an E mail to him via E Bay with a request for quantity costs and
his actual e mail address but he has yet to
respond which is not really a good sign. I usually enter a search for '
telescopic fishing poles crappie'
so I am sure that over time another vendor will pop up. I will check into my
records later when physically able and will certainly pass it on to you. As
an aside I remember that one particular shipment was marked "shooting star"
but I suspect that names may change by year.
I note that others gave some links but they do not pertain to the fishing
poles that I recomended.
Regards
Art

"Play with words if U like."

The whole phenomenon is not static. The incident and reflected waves move. It is their interference patterns, the standing waves, which are static.

Cecil wisely called them the rms values. I assumed it understood that the RF (a-c) voltages and currents are expressed as their rms values unless otherwise specified. Everyone should know that a-c is an acronym for alternating current which, of course, alternates,

i dont' know if i would really call them 'reflectors'. from the shape and spacing i would think they were more of a vertical ground screen behind the monopoles. kind of like having a dipole mounted above a ground screen, it would provide some directionality outward and shield them from noise from the building inside.

I stand by my statement, " 6dB doubles your range". Rather than going to an obscure site and referencing something about some TV coverage - just run the numbers. We are not talking about broadcast to consumer TV sets here. Anyone who has done path analysis knows that 6dB doubles the range. Check into it - you might learn. On second thought here is the equation -
Loss (dB) = 36.6 + 20 log F (MHz) + 20 log D (statue miles). And, again, as first stated, " within the limits of the radio horizon". Off course, space shuttle mobil and EME folks don't worry about the horizon.

Came across a vintage Hy-gain beam in excellent condition with the four inch diameter black traps. I think this beam is from the late 50's. Need element length and spacing dimensions. Missing the gamma matching sections so will need configuration for the matching the single length driven element. Would be great to get a copy of the assembly and installation instructions.

Any help would be appreciated.

Larry

Larry:

I bought one of those when they first appeared, and put it up. The traps lasted only a few months, before they sucked
water and detuned. I am still using that antenna with the replacement solid traps they provided as warranty
replacement. I'll bet Leo really lost big time on that first design.

Unfortunately, I cannot find either the original instructions, nor the later dimensions which came with the replacement
traps, but bottom line is that those black traps were a problem waiting to happen.

# 2117. Re: Facts

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-10 04:48:39 UTC
From: Frank <ve6cb@NOSPAM.telus.net>
Message-ID: <H4hkd.141267$9b.112169@edtnps84>
Source record: 86863

Modeled #14 AWG, copper conductor, 32ft monopole, 29 radials of 25ft, and
base 6" above (nominal lambda/1000) Sommerfeld/Norton ground of Er = 13,
sigma = 0.013 S/m at 1.8 MHz. All segments 6".

NEC2 computes:
Zin = 2.87 - j1358 Efficiency 92%

RADIALS2 computes (with radials 1mm below ground):
Zin = 1.55 - j1310 Efficiency 23.5%

Not a large amount of difference, but thought I had gotten closer results
with a different monopole, but seem to have deleted the code (Not sure why
such a large difference in efficiency). NEC2 is supposed to provide a
reasonable approximation of a buried radial monopole when at about
lambda/1000 above ground. Be interested in any comments, and what NEC4
provides if anybody has it.

73,

Frank

twarnt no problem - if the dipole was 'clean' the double-dip may be due to
how close you were to it, the coax length, a nearby object, - your presence
near the antenna, the way you held your mouth while taking the measurements,
the measurement methods themselves, a passing cloaked Klingon bird of prey,
an ionized whif of exhaled air, or something none of us have ever seen.
(many causes - most just accept it is as - in Walter Cronkite's words
"That's the way it is.")

Art Unwin wrote:
"So how does one "create" several conductive surfaces of what ever
length on a continuous electrical surface?"

First examine the ways it has already been done and ask why? A non-resonant reflector provides a much wider bandwidth than a resonant reflector as used in an array like a yagi, for one thing.

Plenty of grid-dish, corner-reflector and similar non-resonant reflector antennas are in use to reduce wind-loading. You have no need at lower frequencies to use solid reflectors. Surface irregularities are not much problem. The solid dishes at 2-GHz are built that way for convenience, not because they need to be. The same is true at lower frequencies. At higher frequencies, the conductors are so close together, there isn`t enough reduction in wind-loading to be worth the construction effort required with grid-reflectors.

Grid reflectors only need a collection of conductors parallel with the radiating element(s) illuminating (driving) the antenna, and placed for best results. Reflecting elemants in a grid reflector placed perpendicular to the driven element don`t work. Curvature is used tn dish reflector bars for focus. An angle is used in the corner-reflector for more gain than a flat reflector. None of the reflectors needs cross-connections between the reflector bars anymore than ground radials need their far-ends interconnected. Such connections allow eddy currents which only cause loss. The only current of value is that in the direction of the ground radials or in the direction of the reflector`s parallel conductors, as the case may be. So the eddy currents are bad.

Spacing between reflector bars is related to wavelength and capture area.. Measure it in a good grid antenna and scale to your frequency. Or, see Kraus for capture area etc.

Best regards, Richard Harrison, KB5WZI

Of course the higher efficiency is due to NEC calculating only the I^2R
losses, and not the TRP. TRP should be fairly easy to calculate since the
pattern is "phi" independent. Have not checked to see if there is a TRP
card.
Note that a 32 ft monopole mounted on a perfect ground has an input
impedance of 1.58 - j1311 Ohms. The efficiency is reduced to 86% due to
increased I^2R losses.

----------

I've checked, thanks.

The field strength values I posted are based on empirical data used by the FCC to determine coverage range, and protection ratios for FM & TV broadcast stations. The same physics applies to "hams" as to broadcasters.

The free-space path loss formula over a reflection-free path gives different results. But, as the original post asks " Is it worth it? Will I notice?," the real-world values from the FCC curves will give more applicable answers.

Verify my numbers and conclusions for yourself at http://www.fcc.gov/mb/audio/includes/curves.html .

You might learn <g>.

Crazy George`s information on the Wullenweber is great. I have no information on this monster but a pair of loops or Adcock directional antennas can be mounted perpendicularly and their outputs can be connected with a goniometer to provide the effect of rotating the directional antenna while the array remains unmoved in place. Terman shows how on page 1051 of his 1955 edition. Could our military be extravagant with taxpayer money?

What makes a double dip a bad sign? Most antennas have many.
What does any dip have to do with non-optimal return loss? By
definition a dip in SWR indicates better return loss.

Chip, N1IR wrote:
"Not in 1947 edition (sad face)."

Too bad. Authors neeed new additions to new editions so owners will upgrade.

Terman`s topic "Goniometer" starts on page 1050 of his 1955 edition. His illustration is Fig. 26-29: "Crossed loop antennas connected to goniometer."

Each loop`s feedline is connected to a fixed goniometer coil and these are crossed at right angles. A rotating pickup coil is mounted inside the fixed coils and shares their axis. The output to the radio is taken from the goniometer`s rotating coil. Terman writes:
"Thus the rotation of the goniometer secondary is equivalent electrically to rotating the loop (or Adcock) antenna."

In 1960, the chief of our Argentine oil exploration and production called me into his office on Tierra del Fuego to ask me if Dr. Maldonado, our physician, and not Alec Eussler, our atomic physicist (aka radio technician) should be ordering the goniometer.
Our chief, George Blackwell thought the goniometer was diagnostic equipment for a social disease.

Forgot to add that dipoles are resonant near all odd
half-wavelengths, i.e. 0.5WL, 1.5WL, 2.5WL, 3.5WL, ...
They are also antiresonant (purely resistive) on all
integral wavelengths, 1.0, 2.0, 3.0, ...

Using a Smith Chart, if one plots the feedpoint impedances
of a dipole VS frequency and connects the dots, that locus
of points will describe a (very rough) spiral. (Traversing
once around that rough spiral from resonance to resonance
is one full wavelength, not 1/2 wavelength.)

I'm not aware of any vertical antennas with cloverleaf patterns
so I am going to assume it is a horizontal antenna (as used for
BC shortwave).

A horizontal dipole longer than 1.25WL tends to have a multi-lobed
radiation pattern, at one point, resembling a cloverleaf. Such a pattern
is pretty much four-lobed when the dipole is about 1.6WL. At shorter
wavelengths than that, it exhibits more than four lobes and at high
multiples of the 1/2WL resonant frequency, becomes essentially an
end-fire antenna.

KF6HHS wrote:
"I stand by my statement: 6 dB doubles your range."

The "Sommerfeld formula" is ancient and accepted. It says:
Ground-wave field strength = (A) Eo / d
Eo = field strength at the surface of the earth at a unit distance from the transmitting antenna, neglecting earth`s losses
d = distance to the transmitting antenna
A = factor taking into account ground losses

If the earth is perfect, the above reduces to:
volts/meter = Eo / d
assuming the right scale factors.

At twice the distance, the field strength over flat earth is halved.

The resulting current is also halved. Thus, the power, their product, is quartered. That`s a 6dB change from doubling the distance.

On the other hand, if you want to produce the same field strength at twice the distance, you must use 4X the power by the Sommerfeld formula.

Best regards, Richard Harrison, KB5WZI

On 10 Nov 2004 20:16:40 -0800, radio913@aol.com (Dr. Slick) wrote:

> A double dip in a very narrow band, like 88-108 MHz
>for example, is a real indication of something wrong.
>It has always meant that the maximum return loss suffers.

Well, for openers, and by your own description of a "garden variety dipole," you don't have the prospects of anything but a narrower band than 88-108 MHz (even if you opt to match directly to 73 Ohms). A "garden variety dipole" centered in this band will only match 73 Ohms from 89.5-99 MHz - it will only match 50 Ohms from 90.5-97 MHz.

As for "double dipping" none of your posts to date have any facts to test your complaint. If we are to assume these two dips occur within the same band, that is actually to your benefit as it could only enlarge the matching prospects. However, your paucity of details leaves this as speculation on both sides. If the two dips occur within and without the band, then you have offered nothing to distinguish this from the natural order of things. Simply put, ALL dipoles have many dips throughout the spectrum. In this regard there is nothing special about your "double resonance."

As for the disparaging comment of "maximum return loss suffers," that too is in conflict with expectation. There is nothing inherently sufferable about having more than your share of "dips." Additional resonances does not detract from any other resonance's capacity to perform within its region of match. A second resonance doesn't necessarily rob another and it could be argued that it is actually a boon if you wish to enlarge the bandwidth of an antenna (which by your only specification of 88-108 would be a positive feature).

Now, as to HOW you could achieve TWO SWR dips within the FM broadcast band with a "garden variety dipole," then that is revealed by your comments about not needing (and by inference not having) your driveline choked. Simply put, it sounds distinctly like your transmission line length (combined with velocity factor) added a resonant circuit in parallel with the dipole to offer this second dip. You munged things around with the antenna, but changed lines and the second dip went away (as a function of a different line length, or its becoming balanced or choked). You would have to have stumbled onto an unique antenna design to have forced these two dips into this FM band and this is negated by your own description of a "garden variety dipole." On the other hand, transmission line common modality is as common as rain in Seattle.

Hi Richard,

Unfortunately, from FCC field data for BOTH AM and FM curves over real earth, they show anywhere from 6dB to 20dB+ depending on range from the transmitter. In most respects departure has to do with earth curvature and earth soil conditions. Even sea water paths do not recover the greater than 6dB requirements.

"Awwwwhhhhhh Irv, everyone has a senior moment now and then."

That`s my experience.

Arnold B. Bailey in "TV and Other Receiving Antennas" is more thorough than most. Bailey writes on page 291:
"We have already seen that such conditions (efficient operation) can exist for many resonant lengths of the rod. The rod if divided into two sections and connected to a load at its center, will exhibit resonance when the total length of the rod is any multiple of one half-wave. ----only two resonant lengths will give a simple directivity pattern --- if the rod operates at its fourth resonant frequency, no signal is picked up from directions broadside to the antenna in contrast to operation at its third, second, or first resonance. Only at first resonance is the directivity pattern as indicated by Figs. 6-20 and 6-21.

At all other resonances above the first, the pattern is going through a progressive change which will later be more explicitly shown in a quantitative manner."

On page 348, Bailey gives radiation resistances and drivepoint resistances for dipole resonances 1 through 10, and shows their current distribution patterns.

Best regards, Richard Harrison, KB5WZI

Dr. Slick wrote:
"I`ll give you the harmonics, but a double-dip at for example, 88.1 and 93.7 MHz would indicate a BIG problem!"

Does the dipper dip on one of these frequencies in te absence of an antenna?

Is the receiver connected to the antenna, and can you move one of the dips with the receiver tuning?

Does augmenting the antenna cable move one or both dips?

Does relocating the antenna change the dips?

There seem to be two coupled resonant circuits.

Richard Clark is correct. The FCC family of propagation curves shows greater attenuation than results from signal spreading into an ever enlarging volume. However, these curves also include an inverse distance line which is the 6 dB per doubled distance line. Its drop, make that decline, only derives from the growth in volume the fixed amount of expanding signal fills as it propagates.

Best regards, Richard Harrison, KB5WZI

I've made and used a cloverleaf antenna for 2m in a RSGB 2m Trophy contest.

Used two of them stacked for extra gain.

Results were very good and allowed up complete coverage of the UK.

I Remember back in early 60's a number of hams in my home town built
clover leaf antennas for 2 & 6 meters.. if my memory serves me right
they were horizontally mounted and worked quite well for 2 & 6 Mtr AM
in those days .. I used one as a novice for 2 mtrs. Novices had 2m AM
priviledges back then. But I had nothing to compare it to so can't say
it was better or worse tnan any other 2m antenna. Also if memory serves
me right it was mad up of 3 heart shaped full wave loops condected in
paralell and fed with a single coaxial line.

## 2156. Shielded loop antennas, one last time

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-11 17:24:07 UTC
From: Joel Kolstad <JKolstad71HatesSpam@Yahoo.Com>
Message-ID: <u8SdnYf4fvhWAg7cRVn-2A@comcast.com>
Source record: 86751

I went to the library and took a look in Johnson and Jasik's "Antenna Engineering Handbook," where a good explanation of the shielded loop antenna is provided. In brief, what happens is that the incident magnetic field induces a current around the _outside_ of the shield and -- due to the slit in the shield -- the current is then forced to flow "around the edge" and onto the _inside_ of the shield through whatever impedance it sees at the slit. If you're using a piece of coax where the center conductor has been shorted to the shield at the location of the slit, the impedance looking into the slit is the load impedance 'transformed' back the length of the transmission line (i.e., assuming a matched load, it would be the same as the transmission line impedance). If you're using a coil of insulated wire inside, e.g., a copper pipe, the slit impedance is pretty much a short circuit (well, a small inductance, actually -- the self inductance of the inside loop) so all the current induced on the outside is 'mirrored' into the inside. This then couples into the coil of insulated wire just as if the shield weren't there. Some small loss occurs due to the loop inductance and the finite conductivity of the shield. (I've found web sites with measured results showing that shielded loops do have readily measurable loss over unshielded loops.)

An interesting result of the above is that the polarity of the voltage coming out of a shielded loop should be opposite that of what's coming out of an unshielded loop. (Because in the case of the shielded loop, as the current flows over the edge of the slit it's reversing direction.) It would be fun to try this experimentally... (I'm thinking something like building another coil and discharging a capacitor through it to induce spikes in the antenna.)

The explanation on web sites about the shield acting something like an electric dipole doesn't really fly, IMO.

---Joel

Hi Joel,

Build two loop antennas: one shielded, one un-shielded. Combine them
and see if the cancel (less the differential you've observed as loss
at various web sites (which bears reporting here)).

Yes, a phase reversal is produced by the change of current direction between the outside and inside surfaces of the loop shield. But carry your logic a bit further. There is a second phase reversal provided by the inductive coupling between the inner surface of the loop shield and the wire loop inside the shield.

The wire loop is the secondary of a transformer. Induced and counter emf are 180-degrees out of phase with the primary or source emf. For graphics see Fig. 5-14 on page 79 of Robert l. Shrader`s "Electronic Communication".

Never said they were, and until these recent posts, we all had to
guess. And besides, not all antennas are harmonically resonant.

> A broadband antenna usually doesn't have as good a
>match as a dedicated antenna.

You have too little exposure to the world of antennas to paint them
with that broad brush. A simple example is a discone antenna which is
a variant of the biconical antenna, which is the genesis of ALL
dipoles. Either the discone or the biconical display a very wide
bandwidth (octaves) and are eminently matchable by definition.

>This is why when i
>had two dips, the min. SWR was NOT as good as when i
>had only one resonant (not incuding harmonics) freq.

You have yet to disclose what SWRs were present to make this a
problem.

> Again, didn't need a choke for this one.

You have yet to show that it is not your problem, much less the lack
of need (which is a strict requirement for tuning). "Not needing" it
can be accomplished through one of two means:
Luck,
or
a hardwired solution (the customer, like with CB whips, cannot
vary the length without causing a major shift in dynamics).
Either way, the two are probably the same solution, an even halfwave
multiple length line. The longer the line, the more tenuous the
solution.

> Someone infered the first problem, not high
>above off the ground.

Which will broaden the response (lower the SWR) if too close.
Proximity to ground will shift resonance too, but not add resonances.

Your problem was feedline related. You simply (and without taking
note of it) changed that along with the melange of other activity and
pushed the "problem" up/down the spectrum. The addition of the other

dip is harmonically related to a structural issue that has a physical dimension related to the wavelength and velocity factor. There is no other way to accomplish this with "a garden variety dipole" except with a short transmission line to a SWR tester (I will bet your test cable was a generic 3 foot coax). Any coax line that is as long as an odd multiple quarter wavelength (1/4, 3/4, 5/4...) of the unusual dip will do the same thing if it is not snubbed at the drivepoint.

Sure, of course... but there's also a (single) phase reversal in the
unshielded loop. Hence the overall difference between the shielded and
unshielded loop is still a single phase reversal. Or do you disagree?

A note for anyone downloading this program (and thanks, by the way)-
At least on my computer, this program auto launchs when you (re-)boot
the machine- the shortcut was installed in the windows start menu.
To prevent this, simply delete the shortcut, or pull to desktop - then
can launch when you want it- without haveing it run every time you
reboot your computer-- Jim NN7K

What I am still not understanding, is since the exponential equations
for voltage and current in a transmission line are identical except
for the Z0 term, how can something happen to the current without
the same thing happening to the voltage at the same time? How can
something happen to the voltage without also happening to the current
at the same time? In a matched system, the voltage and current arrives
at the load at exactly the same time attenuated by exactly the same
amount. But that voltage didn't flow and that current didn't drop???

If one of the four elements doess not have a trap, it could be a Cushcraft A4. Mosley antennas that I have seen put two traps in one housing; so, it looks like there is only one trap per element side unlike the HyGain and Cushcraft that have two. Offhand, I can't think of a Hygain 4 element antenna with traps. I don't know if www.cushcraft.com still exists. You can get to the Hygain stuff from the MFJ site.

Cecil,

If you prefer your voltages to flow and your currents to drop, have at it. :-)

Here's a hint.

In business, politics, crime (sorry for the redundancy), and a bunch of other stuff there is an old saw, "Follow the money."

In electronics the appropriate dictum is, "Follow the electrons."

There is no law regarding conservation of voltage. There is a fundamental law about conservation of change, and an equally strong law dealing with continuity of current.

Go ahead and label a change in current at two points on a wire a "drop" if you like, but don't confuse this change with a drop in voltage. They ain't the same thing.

73,
Gene

I understand it quite well... two non-harmonically
related resonances in a very narrow band (88-108 Mhz) is
a bad sign if you didn't design you antenna for broadband.

Joel Kolstad wrote:
"Hence the overall difference between the shielded and unshielded loop is still a single phase reversal."

Let`s reason together, as Lyndon Johnson used to say. An unshielded wire loop and/or a same size shield-pipe loop`s outer surface when placed in the same RF field and having the same attitudes in that field will have currents which attempt to flow in the same direction. Be it clockwise or counter-clockwise, it will be the same direction on the outside of both loops, shielded or unshielded.

As Joel noted, current flowing inside of the shielded loop has its direction (sense) reversed by the configuration of the shield pipe. As current flows from outside to inside the loop around the butt ends of the pipe at the shield gap, there is a phase reversal.

Current flowing on the outside of the shield toward the gap is flowing away from the gap once it has entered the shield. Also current flowing on the outside of the shield away from the gap, while it is on the inside of the shield it is flowing toward the gap. This is a 180-degree phase reversal between current on the outside of the loop as compared with that on the inside of the loop, This results just from current flowing around the butt ends of the shield pipe.

The current inside the loop on the surface of its shield is the primary current in a two-winding transformer.Current induced into the wire loop contained by the shield is secondary current in this transformer.

Transformer secondary current is in the same phase as self-induced current, that is it is 180-degrees out of phase with the primary current. Two phase reversals in the shielded loop place its output in the same phase as the unshielded loop.

Best regards, Richard Harrison, KB5WZI

Joel, think of it this way... Consider the "shielded loop" in which
the gap is at the top, and the left side is a piece of coax. The
outer of the coax is just the loop "shield" on the left side. The
coax center conductor connects to the right side of the loop "shield"
at the top, across the gap. So the current in the coax center
conductor is just the same as in the shield right side. In other
words, for a loop which is very small compared with a wavelength (at
least), the current in the center conductor is the same as the current
on the outside of the left half of the shield, and in phase with it.
In other words, it's the same as in an unshielded loop. I don't see
any phase reversal there.

Or consider it this way: the loop encloses essentially the same
time-varying magnetic field, whether you look at the loop formed by
the "shield" or the loop formed by the wires inside the "shield."

Cheers,
Tom

I still have such an antenna -- for two meters. It is the Cuschcraft Big
Wheel. It consists of
3 vertex-rounded triangular elements. I think they are a full wavelength
with one side of each
connected to the center conductor of the coax and the other side of each
connected to
ground. So it looks like a cloverleaf. It produces an omni-directional
pattern. My antenna has four of these stacked with phasing harnesses.

The original inquiry mentioned for use at broadcast frequencies, so I doubt
that the Big Wheel
is what is meant.

Here's something for virtually nothing. Take a
commercial FM folded dipole, vary the feedline length,
and you have a tunable folded dipole peaking at your
frequency of choice. The tuning can be done by mounting
two telescoping antenna sections side-by-side.

You are going to have to look very carefully at construction details to determine brand, and then at various differences
due to age to identify the specific model. Then go to the URLs listed for drawings. Just yesterday I was asked to sort
out a 6 element antenna, which turned out to be a HyGain TH6DXX with several TH7DX repair parts. The original TH6 boom
to mast hardware was notoriously weak, and was often replaced with the later, stronger TH7 assembly, but the
documentation on that modification is very obscure on the 'net, so the relatively inexperienced (re-) assembler was in a
quandary about the model, and consequently the dimensions.

In spite of other misinformation you have been provided, HyGain built a 4 element trapped antenna, the TH-4, sold in
several versions between about 1956 and 197?. See another posting 11/09/04 on this ng asking about one.

Nilla Wafer wrote:
"Were the two halves of the dipole of equal length?"

The adjacent close-spaced wire ends have much mutual resistance and in most cases there os a considerable conductance between them too. In these cases, they resonate as a unit. But, imbalance enhaces radiation from the feedline which can produce a separate resonance.

Thank you.
Is this old book the only with a description of this antenna?

I found a pic from the WNEX Antenna:
http://www.theinternetfarm.com/goodtimer/wnex/wnexhist5.htm

Is there a scan from the pic in the book in the net?
Its very old, it should be free?

Why is this type of antenna not in use?
I know, the Big Wheel is a very good construction and very popular.
What was the advantage of Smith's cloverleaf antenna?

Hi Richard.

However, out stellar designer has managed to negate that through a "marijuana garden variety dipole" with radials. ;-)

I wonder who would be more interested. The DEA or the PTO?

Morons like you, and diatribes like this, simply reinforce my commitment to our way of life.

Every now and then it becomes necessary for someone to stand up and make other accountable for their actions, or, lack thereof. We do that while most of the world sits back and watches. There are Alfa Countries and Beta Countries and I think we Americans can get along fine without the Beta Countries. They're weak, they have no resolve and they are not willing to step up. Have we and will be make mistakes? Sure, but, that happens because we are human and as such we are prone to making mistakes. However, is the world better off in the long run because we step up? Damn right they are. Start counting the interventions and therein lies your answer. And, to you, Mr. Coward who won't ID yourself, let me tell you one thing; you are likely safe and secure because of us. Is that arrogance on our part? No, that's being accountable, something you're not, and something most of the rest of the countries of the world aren't either. Go ahead and balk at the Saddam's of this world and see where it gets you.

Hi,

Could someone please provide a correct near field equation that a computer programmer can understand? I'm using the following equation in a simple simulation but it's not working in all cases.

E = a * sin(theta) * q / ( 4 * pi * e * c^2 * r )

The computer program uses the above equation to create tiny segments of oscillating charge. The program simulates a wire carrying current and a ferrite material. The way I am simulating the ferrite material is by placing small loop currents.

According to the above equation, the near field from an infinitely long wire should not change with distance. That is, the near field at 1 inch should be the same as 10 inches. This also agrees with the near field results of an antenna-designing program. Now if that's true, then how can an infinitely long wire generate a net voltage across a closed circuit? If the electric field is uniform then the net induced voltage around a closed circuit that is near the infinitely long wire should be zero. But experimental results show that to be completely false. OK, I couldn't find an infinitely long wire, but a pretty long one. I entered the exact dimensions of my experiment and the simulation results were completely off from the experimental results. In fact, there was significant induced voltage from a very long wire.

Can any one please shed some light on my error? BTW, the simulation successfully predicted several other experiments when the theta angle was zero. Obviously the theta angle goes from zero to 180 degrees in an infinitely long wire. Am I using the wrong equation?

Any help is greatly appreciated,
CJ

No. The new 3rd edition of "Antennas" also has the "clover-leaf" on page 726 along with several similar types.

I`ll speculate that the horizontally polarized omnidirectional antenna has faded in popularity due to so many automobile FM radios in use. Vertical or circular polarization may be better for line-of-sight propagation to an automobile which is equipped with a vertical car antenna.

Best regards, Richard Harrison, KB5WZI

From the calculated field strength (as a function of Theta) the TRP for 100
W input, which includes copper and ground losses, shows 27.4 W, or 27.4%
efficient. In very close agreement with the RADIALS2 program. The only
noticeable discrepancy appears to be in the real part of Zin.

Bob- this on 1200 MHz celeron- with windows "XP", service pack 2, and all upgrades. Made by E-systems, and has some quirkies- notably, when running some DOS based software (like ARRL's "Microsmith", it generates graphic trash in the results column), but this was not something I have seen before.

Internet browser is Mozilla 1.7.3, and this was NOT downloaded from QSL.Net- got the copy from the gentleman that placed on his webpage, as was like mollassas downloading off of qsl.net . Also, it is 1.4.0, NOT version 1.5.3 (dont know if that had provision to place the shortcut into the start menu). But, after downloading, and then rebooting, was surprised to see it running. Turned out this was solution. Jim -NN7K

Dear Jim,

I have completed a test installation of the ver 1.4 on a Windows XP
system, and I think I can explain what must have happended during your
installation. There comes a point in the installation where the
installer presents a list of different Start->Programs folders for you
to choose from. By default it shows SmartSmith as the selected folder.
However, directly below that is the folder "Start Up". I have to
assume that you inadvertantly selected the "Start Up" folder instead
of leaving it at the default.

Frank, as you say, the height of the radials in the NEC2 model is only 6 inches above ground.

The radials are shallow-buried in the RADIALS2 model. It can't do elevated radials.

The ground loss resistance as height decreases, as seen by the antenna, increases very fast percentage-wise as the radials get within a few inches of the ground. It is due to very close magnetic and electric coupling to ground. Radials are transmission lines, insulated from but running very close to a resistive slab of soil.

This would account for the computed higher input resistance of the radials ( 3.5 - j*3.3 ohms ) ( for 29, 25-feet long radials. Rg=77, K=13 ) in program RADIALS2.

The calculated antenna input impedance in RADIALS2 is that of the antenna alone. For feedpoint impedance add the input impedance of the radial system. Presumably, NEC2 does not compute the input reactance of radials.

Efficiency is calculated in the usual way from the sum of antenna input resistance and radials' input resistance.

If you contrive to change the radials input reactance without changing frequency or the antenna, you will notice the loading coil tunes it out along with antenna reactance.

Incidentally, when elevated radials are near the ground their velocity factor decreases fast which makes a mess of the usual recommendation to prune them to 1/4-wave free-space length.

When radials are actually lying on the ground surface the velocity factor decreases to roughly 0.5 of the velocity of light. When buried the underground VF can fall to as small as 0.15 depending on soil permittivity. (or moisture content.)

I have a Hy-Gain TH-3MK3 (Thunderbird) and the rubber end caps for the traps have weather rotted.
Does anyone have a sugestion for an alternative or a quick fix for replacements.
I know, I can order them through Hy-Gain. I do have some time issues.

Thanks,
Kirk

Reg, thanks for the info. I see I was making an error with RADIALS2. Did not realize that you had to add the radial impedance to the antenna impedance; I thought it was computed in the final result. I figured something was weird since the input impedance was similar to the antenna modeled over a perfect ground. NEC2 does compute the input impedance of the complete structure, but as mentioned before it is limited, in that all wires must be >= lambda/1000 above the ground (at 1.8 MHz about 6"). I am just starting to delve into computational electromagnetics, so do not know that much about NEC. It uses the "Method of moments" in its computations. The theory of operation manual is available for download at several web sites.

Anyway, with RADIALS2, I now get an input impedance of 5.1 - j1303, and with NEC2 2.9 - j1358. I did try entering a negative number for the depth of the radials, but RADIALS2 did not like it.

Your comments about the effect on the radials of being buried are also very interesting, and obviously indicate the reason for our slightly different results. The very low VF of buried radials indicates that the length is less important.

As for efficiency, NEC2 computes a normalized far E-field at 1 meter. For phi independent structures it becomes trivial to integrate the power density over a hemispherical region to arrive at the true total radiated power. 100 Watts into the antenna radiates 27 Watts, again, very close to RADIALS2' computed efficiency of 23.5%. Come to think of it, I guess I could have estimated the losses -- as you do -- by comparing the input impedance of an antenna over a perfect ground with the same antenna over a lossy ground. Still I think it was more fun playing with Excel spread sheets and coming up with a similar answer.

Regard,

Frank

www.mcmaster.com has all sorts of useful things, including plastic and
rubber caps.

Quick shipping, it is rare that you not not get something from them
the next business day.

Very big online catalog.

Happy trails,

Those are essentially the differential equations used by Ramo and
Whinnery to develop the following exponential equations for load
matched transmission lines (no reflections):

V = V+(e^-az)(e^-jbz)

I = V+(e^-az)(e^-jbz)/Z0

where 'a' is the attenuation factor. So why does an attenuated
voltage drop while a current, attenuated by exactly the same
percentage, doesn't drop?

I think it was shorter lived than that. I have 1962 and 1964 ham catlogs, the TH4 is in the 62 (no picture), but not in the 64. By 1964 the TH5 was out. That is not to say they were all sold by 64. I should have mentioned the Explorer 14, which they call a 4 element antenna, but to the casual observer looks like it has 6 elements.

BTW, Hygain no longer comes up on the MFJ web site. Anybody know if they sold it?

Dr. Slick wrote:
"(1)A properly tuned and positioned dipole will
be resonant at only one frequency.
(2)Double-dips are a bad sign, and the return loss suffers."

(1) - Nope, just not true.
(2) - Not true either. (see #1)

With the two 'dips' not being harmonically related, it
appears that there is some 'other' reason, the feed line
for one, or something near the antenna (a person for instance?).

Shepard Hardware Products
Three Oaks, Michigan 49128

A well stocked hardware store (and some Home Depot/Lowes) will have these
usually in White (instead of black) in 1" to about 2" in 1/4" increments.

I usually find them as:

Crutch tips, shower rod end caps; galvanized fence post vinyl cap.

KEY ATTRIBUTE IS TO FIND -- UV resistant product -- which reduces
outdoor/sunlight effects.

Carl -

You will find that MFJ/Hy-Gain does not have all of the manuals on-line
(e.g. TH-4 model). Unfortunately, the manuals/documentation for early or
short lived Hy-Gain antenna models are not in the possession of MFJ/Hy-Gain.
These were likely lost in earlier ownership changes or accidentally thrown
out through the years.

This is not a problem unique to MFJ/Hy-Gain. Bencher had a similar problem
with early documentation after its acquisition of Butternut antenna line
from the previous owner.
Cushcraft does not have manuals for some of its very early vertical and beam
designs (short lived).
The owners of these antennas could perform a service to the amateur
fraternity and send copies (or PDF scans) of their documentation to the
current owners, with the stipulation that it be posted for all.

He said something about radials. Radials not attached to the
antenna are like parasitic elements. Two shorter radials will
resonate at a higher frequency than two longer radials.

I know hy-gain.com works, but you can't simply get to it from
mfjenterprises.com. Used to be able to. If you type in Ameritron or Mirage,
they come up with several choices. Hygain and Hy-gain give you no match. I
did finally get it to work by searching on "rotator", and then clicking on 6
meter beam. This shows Hygain at the top of the page together with
Ameritron, Vectronics, Mirage, and MFJ ( I am not claiming this makes
sense). If you click on "antennas", you only get the MFJ.

# 2227. Putting a Ferrite Rod at the Far-End of a Random Wire Antenna ?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-13 17:24:08 UTC
From: rhf-newsgroups@pacbell.net
Message-ID: <ff3145e8.0411130924.6a68d0be@posting.google.com>
Source record: 86624
Cross-posted to: rec.radio.shortwave,rec.radio.amateur.antenna

FO&A,

Here is my Question: Is there any sense in putting a Ferrite Rod
at the Far-End of a Random Wire Antenna with the Wire from the
End of the Wire Antenna Element 'wrapped' around it in a
"Tuned Coil" to improve the AM/MW Band Reception ?

* Any 'theory' behind why this Idea might Work ?

* Does this Idea actually Work ?

* Or is this Idea just so much Antenna 'hype' and Sales Marketing

I am Asking these Questions is because of what I have read about
the RF Systems "EMF" Electro-Magnetic-Field Passive Wire Antenna
http://www.universal-radio.com/catalog/sw_ant/0743.html

In "John Wagner's Shortwave Tips & Tricks" he writes:
http://www.dxing.com/tips.htm
"The EMF antenna has two 35mm film canister looking objects
connected to it. The canister on the Far-End is actually an
excellent "Tuned Ferrite Rod" designed for MW (Medium Wave)
and really helps any receiver without a built in MW Antenna
Rod. Canister two (in middle) is a Balun that helps SW
reception very much."

i want to know ~ RHF

# 2228. Re: Is it worth it? Will I notice?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-13 17:35:32 UTC
From: "J. Mc Laughlin" <jcm@power-net.net>
Message-ID: <10pchct7pjfn878@corp.supernews.com>
Source record: 86625

A long time ago, when there was not so much man-made noise, I found that in the almost-flat-country at the extreme edges of coverage from a base station to a mobile station, the rate of decrease was roughly one db per statute mile. This was in the 160 MHz range.
The mobile is so far away from the base that the received signal is "noisy." I am considering rural locations and a terrain without significant hills.

On the average, +3db of power at the base provided another 3 miles of (poor quality) coverage. More often than not, coverage was limited by the transmitter power of the mobile and the noise level at the base!

The question asked can start to be answered when one knows the value placed on increased coverage.

It would probably help if you posted the length of the boom and the length
of the longest element. Are you saying there are two driven elements?

I took a look at the antenna you're describing...

"RHF" <rhf-newsgroups@pacbell.net> wrote in message
news:ff3145e8.0411130924.6a68d0be@posting.google.com...
> * Any 'theory' behind why this Idea might Work ?

My thought would be that, at MW frequencies, the 'wire' part of the antenna is pretty much 'lumped' (no significant phase change along its length), so you have a standard ferrite rod antenna that you're hooking up via a long piece of hookup wire. That's a reasonable enough antenna.

As you approach HF, the 'wire' part of the antenna starts to become active and the two signals combine.

Still, this is very much a 'hands waving' explanation; hopefully someone else will have a more solid response.

> * Does this Idea actually Work ?
> * Or is this Idea just so much Antenna 'hype' and Sales Marketing

I imagine it works as well as either antenna alone (the ferrite rods or the long wire) would, and the real question is... do the two together produce any significant additional gain? I suspect not (much), but even if so, sometimes a wideband standard gain antenna is more desirable than a higher gain single bander.

>the RF Systems "EMF" Electro-Magnetic-Field Passive Wire Antenna
>http://www.universal-radio.com/catalog/sw_ant/0743.html

For $95, who would be tempted to clip off that sucker at the end and discover it didn't amount to a hill of beans? Self-fulfilling illusion of value perception.

>In "John Wagner's Shortwave Tips & Tricks" he writes:
>http://www.dxing.com/tips.htm
>"The EMF antenna has two 35mm film canister looking objects
>connected to it. The canister on the Far-End is actually an
>excellent "Tuned Ferrite Rod" designed for MW (Medium Wave)
>and really helps any receiver without a built in MW Antenna
>Rod. Canister two (in middle) is a Balun that helps SW
>reception very much."

Are we to believe John cracked his wallet open to then crack open the film canisters? As far as guesses goes, this is as good as any; but given the techno-drivel that populates the rest of the page, the going doesn't go very far at all.

>i want to know ~ RHF

Ah, but that would cost you $95. You would have to first discover what "designed for MW (Medium Wave)" actually means. Given the manufacturer explicitly states nothing in that regard (devoting most of the coverage to a BalUn) and calls it a "magnetic module."

Consider, if it is "designed for MW (Medium Wave)" then it is neither designed for LW nor SW, and yet the ad clearly states "covering 100 kHz to 30 MHz." Such contradictions are a clear warning with red

lights and flags waving. If it is designed for "covering 100 kHz to 30 MHz," then the doo-hicky at the end is probably more useful as a monkey-fist for tossing it up into a tree.

Anything that will increase the current in the wire below top-loading
is a good idea.

> * Does this Idea actually Work ?

I don't know the answer. A ferrite inductor will increase the magnitude
of inductance over an air-core coil and top-loading will increase the
current in the wire part of the antenna. It's an interesting idea
assuming that antennas are reciprocal for transmitting and receiving.

I'll pick door number 3, Monty.

If the far end of the antenna were grounded there might be some pickup
at the self resonant frequency of the ferrite coil, and it would be
a good DC ground at the far end that might reduce some noise.

If it's not grounded, it's just a convenient weight to toss it into
the trees, because there's no loop in the circuit for any current to be
coupled into, and a small isolated ferrite coil isn't going to produce
a voltage differential to ground that could couple through capacitance.

> gain single bander.

Work is not a very well defined word. The antenna will work in that it
will pick up some signal and deliver it to the radio. I think you mean
to ask how well compared to another antenna.

I pretty much agree with what Joel wrote but add the following
explanation. Any time you add some type of coil to a wire you are
electrically increasing the electrical length over the physical length
of the wire. The coil on the end will cause the wire part of the antenna
to resonate at a lower frequency. This is generally not a good or
effective way to make a sensitive antenna but it will "work."

Generally a wire antenna will pick up a significant amount of signal
energy at frequencies above its electrical length and perform much worse
below its resonate frequency so basically this looks like a attempt to
get a rather short piece of wire (16 feet) to "work" down to a frequency

far below its resonant physical length.

The BALAN coil depending on design could be a good thing in that it will cause the high impedance of the wire to be closer on average to the impedance of the coax cable part of the antenna and the radios input.

# 2239. Some notes on UKWtools GPL RF coverage software

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-13 22:39:27 UTC
From: Bob Bob <bcnntp@optusnet.com.au>
Message-ID: <02fi62-9v8.ln1@p400bob.lse.com.au>
Source record: 86635

Mainly posting this so it becomes a record for later lookup by
experimenters.

UKWtools is GPL RF coverage prediction software based on the Longly-Rice
model. It uses a mix of GTOP30/Globe 30 arcsecond data and SRTM 3
arcsecond data (both freely downloadable)

From the website you can download both Windows and Linux packages. -
http://www.qsl.net/g4klx/software.htm

I am not the author of the software!

The notes....

- When I tried to build and install on Suse Linux 9.1 the path plot
function would fail and crash the program. It had worked fine on a
lesser version of SuSE. This appears to be a change in the default
character/language that happened with 9.1. The author mentioned that he
didnt have the same problem with his 9.1 but did say he had compiled his
own WxWidgets. Whatever the case changing the "LANG" variable before
launching the program is a viable workaround. I simply wrote a bash script;

```
#!/bin/sh
LANG=en_GB.ISO-8859-1
cd /usr/local/bin
/usr/local/bin/ukwtools
```

launched that, and the problem went away.. The original LANG variable
was "UTF-8" but since you are only changing it for running this
programme it wont hurt anything.

- Since I am moving to the US early next year I had a look at modifying
the code to use the higher resolution SRTM (1 arcsecond or about 30m
tiles) data available. I found that modifying the two lines in App.cpp
with the SRTM3 grain settings of 1201 to that for SRTM1 (3601), it
seemed to work! Note that it is also possible to change the display
window size (not scalable) to different sizes in Defs.h)

Pls note that I havent fully tested this but the terrain looks correct
and a sample coverage plot seems to conform to terain features around it.

If you wish to respond to this post I will be checking. The reply email
address however is bogus. Just substitute bcnuup for bcnntp.

Cheers Bob VK2YQA

Steve,
I use one on my SUV - also used it on a long trip thru South America with great success.
Recommend you tie a fishing line to it when driving fast on highways.
For stationary use I use the new MFJ 12 foot telescopic top in lieu of the supplied one - it really improves the signal on 20, 30 and 40m. The coil oxidizes after a few
months - at least in my climate. Toothpaste will clean it up quickly. Good antenna.

Carl -

Actually, the antenna mounting hardware (boom to mast) and elements to boom
are usually give-aways -- as to who made the antenna. Another area to
carefully visually inspect is the matching system between coax / balun and
driven element.

OK, Jim - all's well that ends well. BTW, it is normal that such files
as the ones from my Win 2000 system might be older than those on a
Windows XP system. I do all of my development on Win 2000 Server, and
it preceded Window XP by a year or two.

Good luck, and be sure to let us know if there are any other
questions, bugs, etc.

There will be a new release within a week or so, if the beta testing
goes well.

Hi Kirk,

What the others are pointing you to are just plain caps that would be
suitable for the end of the antenna elements, not the trap caps that I
think you are looking for.

I think I have a full set of them here. A couple of years ago I
ordered them from Hy gain. (not cheap!)

In disassembling the elements to replace the caps I found that all the
inside insulators in the traps were rotten too. The antenna was shot.
The cost of the new plastic inside insulators was horrendous. I stuck
the whole thing in the garage. Never did install the new caps. They
are in a box somewhere in the garage. Incidentally the antenna had
been stored inside for about 20 years, where all the plastic just
rotted.

Let me know if you are interested in them. Email me at
garyschafer@comcast.net.

JK, RC and CM,

I want to Thank Each of You for your replies to this question.

Note: I am only talking about a SWL "Receive Only" Antenna here.

I suspect that may be one reason that this Far-End Loaded AM/MW Coil may work is the fact that the RF Systems EMF Antenna is 'only' Sixteen Feet (16') Long; and the Two Inch to Three Inch (2"-3") Ferrite Rod at the End of the Wire Antenna Element does have some 'measurable effect' on improving the AM/MW Frequency Band performance of such a short Antenna.
- Relative Size may be the Controlling Factor for this 'unique' small Antenna

? ? Would this 'trick' work with a Larger {Longer} SWL Antenna ? ?

My more specific point of interest would be in whether using a Ferrite Rod with the Wire Antenna Element Wrapped as a AM/MW Coil around it would have some meaningful effect on a Horizontal Random Wire Antenna that was 75-100 Feet long.
- For a Horizontal Random Wire Antenna ?WHY? 'place' the Ferrite Rod at the Far-End of the Wire Antenna Element ?
- Why not 'place' the Ferrite Rod near the Feed-Point-End ?
- Why not 'place' the Ferrite Rod near the Middle ?
- Why not 'place' the Ferrite Rod near the slightly Off-Center 38%/62% like a Windom ?

What about a "Low Noise' Inverted "L" Antenna that is 45-100 Feet long. For an Inverted "L" Antenna ?WHY? not 'place' the Ferrite Rod at the "Top" of the Vertical Leg where the Antenna Wire Element transitions from Vertical to Horizontal ?
- 15 Feet Up Ferrite Rod AM/MW Ferrite Coil and 30 Feet Out.
- 20 Feet Up Ferrite Rod AM/MW Ferrite Coil and 40 Feet Out.
- 25 Feet Up Ferrite Rod AM/MW Ferrite Coil and 50 Feet Out.
- 33 Feet Up Ferrite Rod AM/MW Ferrite Coil and 67 Feet Out.
Or again here would having the Ferrite Rod and Coil at the Far-End work some 'magic' trick ? and Why ?

in search of some ideas and answers ~ RHF

>small Antenna
>
>? ? Would this 'trick' work with a Larger {Longer} SWL Antenna ? ?

Let's approach this from the usual perspective. Many SWLrs posting here already have the ferrite antenna in their receiver and come here for a boost in signals. The fact that it is so easily accomplished by the addition of that same 16 feet of random wire tossed across the living room rug would suggest just how much contribution is found in the ferrite antenna.

Let's put some numbers to it. With the ferrite antenna a DX station comes in S3, replace it with the wire and it climbs to S7. So, if we start with just the wire antenna with the same signal at S7, and adding the ferrite to pump up da volume to S7+ would this be worth $95 to you? What if by simply adding 6" more wire to the 16 feet gave you that same +?

As a product, it is incredibly cheesy to boot. Look at that clunky pl259 at the end of rg174. C'mon now, are we talking about your granddad's RCA Victor this sucker is going to plug into? That and the lead-in is only 16 feet in its own right? How much profit would be lost to give you a decent length of wire and lead-in?

This at least suggests a more practicable study. Loading coils don't do very much without some form of capacitance above them to draw the current. Putting a coil at the top is a fruitless exercise. It may offer to "tune" but it sure won't sing.

Howdy Y'all:
Chushcraft says that the Ringo Ranger II is the latest design featuring three 5/8 wave radiating elements and an adjustable 1/8 wave phasing stub. My question is why a 1/8 phasing stub? Should it be more like 3/8 or somthing, and why only
one phasing stub, should there not be 2? And is the outside of the coax that comes from the ground plane a radiating
element? This antenna has me scratching my head, any ideas?

Harbin

My target receivers are my Kenwood R-5000, Icom IC-R75, and
Grundig Satellit 800 M. Note with the Grundig Satellit 800 M
when the SO-239 is switch on to use the External Antenna the
'internal' AM/MW Ferrite Rod Antenna is disconnected.

Not worried about the cost since this would be a 'home-brewed'
Antenna with parts I already have.

Looking to add a little more signal to the AM/MW Band area for
improved Weak Signal DXing from the Inverted "L" Antennas.

RC,

I have the two Inverted "L" Antennas and about a dozen 10mm X 200mm
Ferrite Rods to play with. So for me it is a matter of De-Rigging
the Antennas; winding the Antennna Wire on the Ferrite Rod; and
Re-Rigging the Antennas.

Doing a dry run with an extra piece of Antenna Wire; I can get
about Nine Turns per Inch; which would be 63 Turns uniformally
wrapped evenly over 90% of the Ferrite Rod.

So my 'focus' is on a "Low Noise' Inverted "L" Antenna that is
100 Feet long. Placing the Ferrite Rod at the "Top" of the
Vertical Leg where the Antenna Wire Element transitions from
Vertical to Horizontal. Rig the Antenna Wire Element with 33
Feet Up to the Ferrite Rod AM/MW Ferrite Coil and then have 67
Feet Out to the Far-End. Would this possibly work any better
then having the Ferrite Rod and Coil at the Far-End ? and Why ?

In my 'imagination' for the AM/MW Broadcast Band; the Vertical Up-Leg would act like an Omni-Directional "Tuned" Vertical Antenna (since the Ferrite Rod would be Vertical); with the Horizontal Out-Arm of the Antenna acting like a Top Hat for the Vertical. Then at the Shortwave Frequencies the 'effects' of the Ferrite Rod would become less and the Antenna would simply act as a normal SWL'ers Inverted "L" Antenna.

Now here is another thought; would having the Ferrite Rod with the Antenna Wire wrapped around it at the Far-End of the Horizontal Antenna Element cause the AM/MW Broadcast Band reception to be Directional 'Off-the-Sides' of the Inverted "L" Antenna ? ? ?

in search of some ideas and answers ~ RHF

Yes, I was assuming you had a short antenna and wanted to load
it. The reason for loading a short antenna is to increase its
electrical length closer to resonance and the benefits are much
more pronounced for transmitted signals. Most modern HF receivers
have enough gain to make up for a less than optimum antenna.

Loading a long wire antenna doesn't make much sense.

Actually, MultiNEC allows you to switch between EZNEC, NEC WinPlus+,
4NEC2, Antenna Model, EZNECpro, GNEC, or the standard NEC2 or NEC4
engines. MultiNEC will read MMANA files but not use its calculating
engine.

Cushcraft claims 7 dbi gain. True or not, it was the best omni directional 2 meter antenna I've ever used. A wayward tree limb turned it into pieces of aluminum tubing, but it WAS 25 years old and had been struck by lighting once. I got my $35 worth out of it. I now use a Diamond X50, not quite as good, but not bad.

Back in 1965, when I was 14, I tried many variations on
"Long Wire" antennas. Given my parents back yard was about 60'
wide and 120'long, it is clear that they weren't really "long" at
any freqeuncy below 30MHz.
My uncle gave me some variable caps, Air-dux and two large,3/4"X16"
ferrite rods. I tried wrapping wire around the ferrite and, except
for short, 10' wire antennas, with the rod between the antenna and the
receiver the rod made no differnce. None. And nothing worked as well
as my "standard" 96' wire antenna. I did make some dipoles cut for WWV
on 10 and 15MHZ and they were slightly better in receiving WWVH then

the 96' wire antenna. They made no difference on WWV.
I was able to build a match box with Air-dux and the caps and that really
helped. The radio was a Zenith SW that died that fall. The LO coil developed a short between the primary and secondary and Dad could not find a replacement part. So, for a late birthday present my mom and dad
bought me a Heathkit GR64. It was a gaint step in that it had a "S-meter".
I even tried a antenna reciever matching transformer suggested by an article in Radio-Electronics. Which did not work. It consisted of two air coupled windings sheilded in a soup can. I wish I had known about transformer deisign that John Doty came up with. Dad also bought me a ARRL handbook and I started to understand that antennas where not complete magic.
Just 99%!
Save your maoney and just put up the longest wire you can, be carefull to
keep it well away from noise sources. John Doty's suggestions for a "low
noise" antenna are a good palce to start. Works very well and it is very cheap.
Terry

OK, that would rule out the CushCraft A4, because it is on an 18 foot boom. I found out that the TH4 uses 3 elements on 15/20, and 4 elements on 10. So, one of the elements would not have a trap. But, the TH3 is on a 14 foot boom, which seems to make it unlikely that the TH4 is also.

I wonder if the guy you got it from knows what he is talking about. If it looks like there were only 3 elements, that could well be the case. I recommend going to www.hy-gain.com and downloading the TH3 manual, to see if what you got is similar. Also, that might explain the rods parallel to the boom that you mentioned. I have the TH3 Mk4, and what you described earlier sounds like the hairpin match.

I don't know where you got that equation, but I'm not surprised it's not giving the right answer. In the near field, there are components inversely proportional to r, r^2, and r^3. The equations are too complex to easily write in ASCII, and the terms require some definition. But you can find the relevant equations in Jordan & Balmain, _Electromagnetic Waves and Radiating Systems_, eq. 10-41 and 10-42; Kraus, _Electromagnetics_, eq. 13-49 and 13-50; Johnk, _Engineering Electromagnetic Fields and Waves_, eq. 11-41a and 11-41b; or most other electromagnetics and some antenna texts. Note that two equations are given, one for the radial component and another for the circular (theta) component, which decay at different rates as the distance from the current element increases.

Doug,
Could be one of several depending on when they were purchased or made.
AEA made a 6 meter loop until the later 90's; though I was never too
impressed with it. Have spoken on the air with a couple of guys who
use the KB6KQ as a mobile antenna and they had a decent signal and
indicated the antenna holds up quite well mobile. The three current
vendors I know of are shown below - don't think you'd get a bad
antenna from any of them, they are reputable operations.

Tam has a good point, since the Hy-Gain TH3 has a 14 foot boom, you can
start with its manual (adobe acrobat)
http://www.hy-gain.com/man/pdf/TH-3MK4.pdf

Hy-gain now calls the "hairpin match" a beta match (the match does make a
"fourth" connection to the boom) - this match has changed a bit from early
models. Also remember that the TH3 does not have a supplied balun.
Again, pay close attention to the type of brackets, swaging, etc. in the
manual versus your parts This should identify it as a HyGain antenna

Hi OM,

If you want to resonate it at ONE frequency (the supposed reason for having that lump at the end) then you would need an inductive reactance of
1000 Ohms at the feedpoint to render the antenna a resistive 6 Ohms and a poor average gain of -8.7dB;
or
1000 Ohms at 3' up to render the antenna a resistive 7 Ohms and a poor average gain of -8.5dB;
or
1300 Ohms at 16' up - 7.8 Ohm Antenna @ -8.7dB;
or
1400 Ohms at the top - 9 Ohm Antenna @ -9dB;
or
1900 Ohms 16' out the horizontal leg - 11 Ohm Antenna @ -9.6dB;
or
2600 Ohms 32' out - 12.5 Ohm Antenna @ -10 dB;
or
5800 Ohms 48' out - 14.6 Ohm Antenna @ -10.5dB;
or
10200 Ohms 58' out - 15.4 Ohm Antenna @ -10.6dB;
or
56500 Ohms 64' out - 15.2 Ohm Antenna @ -10.6dB.

You should note the progression of increased inductance required to tune this antenna to 1MHz (ymmv). At any other frequency and bingo, all bets are off. You should also note there is only a 2dB spread (AVC would quickly put that to rest). Also, the numbers above presume you performed the chore of laying out 16 X 33' radials.

Let's compare that to the advertised antenna
9200 Ohms at the bottom - 32.5 Ohm Antenna @ -26.8dB;
or
13700 Ohms at 8' up - 35 Ohm Antenna @ -22dB;

or
108750 Ohms at 15' up - 39.6 Ohm Antenna @ -19.9dB.

This presumes the single lead-in laying along the ground (where most of this Antenna Ohmage resides.

This, further, would put your antenna roughly 10dB ahead (sans loading, and using a simple tuner) of the $95 spread. I hope you notice the parenthetic statement of a tuner - it does the same thing as these loads, and you get to tune to more than one frequency.

I will leave it up to you to determine how many wraps around how many rods would give you 110000 Ohms inductive reactance at 1MHz.
>
>In my 'imagination' for the AM/MW Broadcast Band; the Vertical

>Rod would become less and the Antenna would simply act as a
>normal SWL'ers Inverted "L" Antenna.

Well, let's just test that hypothesis with the load at the top.

What you get is fairly well tuned at 10MHz (SWR 1.7) with omni coverage in both horizontal and vertical. For other bands, of course, a tuner would be useful.

>Now here is another thought; would having the Ferrite Rod with the
>Antenna Wire wrapped around it at the Far-End of the Horizontal
>Antenna Element cause the AM/MW Broadcast Band reception to be
>Directional 'Off-the-Sides' of the Inverted "L" Antenna ? ? ?

NO. For short antennas and low horizontals, there is almost no directionality. What you are attempting to do is to capture the quality of small loops (which are what the ferrites are) of being directional. The signal from the parasitic wire (what is not part of the small ferrite) is going to fill in the nulls and deluge its poorer sensitivity as well. You can of course test this answer by finding a way to answer my question inferred above about how many wraps and how many rods to achieve 110000 Ohms inductive reactance.

Terry wrote:
Is there any sense in putting a Ferrite Rod at the Far End of a Random Wire Antenna with the End of the Wire Antenna Element "wrapped around it" in a tuned coil to improve AM/MW Band reception?"

Frequency selectivity improves signal to noise ratio. Antenna tuning reduces the possibility of receiver input overload. A naturally resonant length for the medium-wave band will be more than 150 feet, so a coil is likely needed to resonate a random length of wire.

Placing a coil at the far end of an antenna increases the current below the coil which makes it more effective. Such an antenna was patented in 1909. A copy of the diagram which was filed on August 10, 1909 by Simon Eisenstein of Kiev, Russia appears in Fig 9-24 on page 9-17 of the 1994 edition of ON4UN`s "Low-Band-Band DXing". Circuit to the open-end of the loading coil is completed by a capacitive hat beyond the coil.

The ferrite rod increases the coil core permeability. This allows fewer turns for a given inductance. A higher Q results in a more efficient tuned circuit. Multiple methods may be used to resonate an antenna circuit. Eisenstein used a coil and a capacitive hat for top loading. It still may not be enough, and can be augmented with other reactances located elsewhere.

Best regards, Richard Harrison, KB5WZI

Generally, adding non-radiating reactance to an antenna decreases
broadband efficiency, although it may increase efficiency over narrow bands.

If the rod does anything at all, it increases the effective length of the antenna. You can accomplish the same thing by physically increasing the wire length. And all that will do is to increase the amount of signal -- and noise -- entering your receiver. Once you have enough signal and noise to overcome your receiver's internal noise, there's no advantage of any further increase, since there's no improvement in the signal to noise ratio. Try disconnecting your antenna from your radio. If the noise level drops when you do, you've got adequate signal strength from the antenna, and lengthening it -- either physically or with some kind of loading -- won't help you hear signals.

The explanation of the properties of the antenna at the distributor's web site is wholly hype and sales marketing. It's a mismash of misused technical terms, which means nothing and and is quite apparently intended to mislead a potential customer and present the antenna as having wonderful properties which it doesn't in fact have. I'd avoid buying it for that reason if for none other.

Richard Clark wrote:
"For short antennas and low horizontals, there is almost no
directionality."

True, assuming the the low horizontal ian`t a Beverage or similar wave
antenna.

Ferrite loopsticks have broadside to the axis of te rod sensitivity as
compared to air-core loops which are sensitive in the plane of the loop.

Daytime MW propagation is via the groundwave which is confined to
vertical polarization beyond the line of sight distance.

An L-antenna is using its horizontal portion as a capacitive hat for its
vertical portion which is the real antenna during the daytime hours.

>What would be the difference in having a solder back or an epoxy?

A splitter which has a solid (or completely seam-soldered) metal enclosure is going to be more RF-tight than one which simply has a poured-epoxy or plastic back. The sealed-metal variety will keep the cable-TV signal from leaking out, and will keep other signals from leaking into the cable feed.

This is beneficial for several reasons, all having to do with the fact that many cable-TV channels use frequencies which are not authorized for TV-broadcast use - they're assigned to other radio services (police, fire, aircraft, amateur).

Signals leaking out of a cable-TV wiring plant (e.g. from a poorly built splitter, or an unterminated port on a splitter or junction box) can interfere with these other radio services. Similarly, a nearby transmitter operating on these frequencies can leak into an open port, mix with the cable-TV signals, and cause video or audio distortion or interference.

Cable-TV companies are required by the FCC to keep their wiring plants "tight", and they usually run "sweeps" of residential neighborhoods looking for signal leakage. If they find it, they'll either fix the wiring fault (if it's outside the building), or require that the building owner or tenant fix the problem as a condition of continuing to receive cable TV service.

CM,

A 100 Foot long Inverted "L" Antenna is not a Long Wire for the
AM/MW Broadcast Band with coverage for 530 kHz to 1700 kHz

* One Wave Length for 530 kHz is 1896 Feet; and 100 Feet at
530 kHz would only be 0.053 WL.

* One Wave Length for 1700 kHz is 591 Feet; and 100 Feet at
1700 kHz would be 0.169 WL.

Like most people I do not have 600 to 1900 feet of space to
string up a true "Long Wire" {One Wave Length} Antenna for
the AM/MW Broadcast Band. So this is why I am 'questioning'
the use of Ferrite Rod Antenna with a Coil as an integral part
of a 100 Foot long Inverted "L" Antenna.

still searching for answers ~ RHF

You don't need a long wire for listening. One a fairly small fraction of a wavelength is probably adequate. If the noise level drops when you disconnect the antenna, it's long enough, and making it longer or adding gadgets to it won't help a bit.

A number of the people posting on this thread are thinking of the requirements for an efficient antenna. Efficiency is important when transmitting, but of almost no importance for receiving. The antenna just has to be efficient enough to deliver more atmospheric noise than you have internal receiver noise. Any more makes no improvement.

This sounds like 20 questions. You are not telling us what you have. One would not expect somebody to measure an antenna at a height of 3 feet. A dipole would have an impedance of around 75 Ohms, which would give an SWR into 50 Ohms of around 1.5:1 Are you using 50 Ohm coax and a 50 Ohm meter? Is there a gamma match, or such, to adjust? Is it a dipole or a folded dipole? Is there a balun? Did you buy the antenna or build it (I suspect the intent would be different)? Since you are using an SWR meter, are you putting enough power into it to get out of the nonlinear range?

## 2285. Propagation forecasts

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-15 05:02:44 UTC
From: Dave Pitzer <dpitzer@sonic.net>
Message-ID: <ULWId.5392$_3.69357@typhoon.sonic.net>
Source record: 86582

Is there any place on the Net where I can find daily propagation reports? I am especially interested in night time propagation forecasts for commercial, AM broadcast band signals.

Thanks,

Dave Pitzer
AM DX-er

Hi Dave,

Possibly, but they are unknown to me, unfortunately (perhaps someone
will clue us both in).

On the other hand (and it won't do MW much) you could reference VOAWin
for HF propagation work (try a search engine). MW propagation
variation seems to have two major variables, Daytime/Nighttime and
Summer/Winter. Beyond that, it is fairly predictable for any of those
four combinations.

I would suggest following the chatter on rec.radio.shortwave. You can
find reports to help hone your prospects, but when I did an impromptu
analysis of some 1500 postings, I found they actually talk about
contacts only about 0.5% of the time.

Richard,

That's for your reply.

Being an avid MW/ BCB DX-er I have found sporatic "short-term" variations within the longer Day/Night -- Summer/Winter cycles. For example, I live in NE Pennsylvania and can regularly listen to WJR in Detroit at night (slightly better in winter). However, for a three-four night period last week, the night signal varied from unreadable to extremely noisy to "gone". I use WJR only as an example. Othe 50,000 watt clear-channel stations around the east coast suffered the same night-time signal degradation during the same three-four night period. Short-term sun-spot activity??? Only thing I can think of. And if so, this activity should be predictable (and reportable) on a very short-term (24-48 hour) basis. Just a thought on my part.

Thanks again,

DP

Hi Dave,

There've been reports of Auroral activity which is an indicator of
solar emissions that disrupt communication. You might want to include
the solar flux reports at:
http://www.sel.noaa.gov/forecast.html

I have a 20 foot straight wire in my garage, that works better for MW DXing than the ferrite rods in any radio I have, due to the fact that it is much further from any noise sources in the house. I imagine the 16 foot wire being sold there would pick up some MW, but I doubt that adding the ferrite bar at the end helps one bit.

# 2291. FCC Amateur repeater database - if any

Gidday

I want to do some RF coverage plots (theoretical) of the VHF/UHF repeaters in East Texas. I am looking for repeater callsigns, frequencies and Lat/Lon of the sites within a 100 feet or so. (Pref in WGS84)

I dont seem to be able to find it in the FCC database. It seems to omit amateur stations altogether.

Can anyone point me in the right direction?

TIA Bob VK2YQA.

amateur stations are in there. but you won't find a list of repeaters.
there may be some really old repeater calls, but they won't have lat/lon
info. to find that information you would have to contact the repeater
coordinating organization for that area who may or may not have the details
you want and may or may not let you have it... they are volunteer
organizations.

MP-1 manual version is what I use.
BTW a fellow islander KK9TT has had similar success with his. I worked him with his MP-1
sticking out of the hotel window in Honolulu with an S7 signal in FL on 20m.
We both never leave without our MP-1 and the IC706 on trips. Great small package. Mine fits together with 115/230 power supply and key/cables/plugs into a PC case. Never had problems in customs or security checks.
Good luck and DX

Pardon the thread drift, but making the receive antenna directional can improve system SNR by reducing the total noise voltage delivered to the receiver input, as a ratio of the desired signal.

You maximize the gain of a colinear by separating the current loops as far as possible ( see the graph in the ARRL Antenna Handbook of gain vs current loop spacing). By making the top element a 5/8, then a 1/4 wave phasing stub ( 1/8 long), the bottom element is realized as an inverted 5/8. This places the current loops 3/4 wavelength apart. (Compare this to 5/8 separation if the bottom element were fred as a traditional 5/8- and require a longer stub) .The bottom of this element is then voltage fed- diminishing the need for radials.

Dave:

Unfortunately, there is no commercial value in MW nighttime propagation forecasting, so none is published. You will
have to educate yourself in propagation theory, and then watch the elements which affect it. In the case of last week,
I believe it was a coronal ejection (from the sun) which arrived mid-week. And, I think the National Radio Club, which
is a MW DX club, is still active (until BPL and IBOC shuts them down). Find them (they are on the 'net) and see what
they have to offer. I suspect they have a bulletin board or reflector for real-time updates on propagation, stations
heard, etc.

If this link doesn't help (I've not checked it out) - perhaps get a hold of
a repeater control Op and ask them who the Repeater Frequency Coordinator is
for that region. Once you find that out, then write them and while getting
info from them, ask about the others in the State. Then from there, you can
contact others. They usually share information to help in solving
Interference problems (hopefully) before they start.

Now that I think about it, the ARRL Repeater guides have Repeater
Freq.Coordinators listed - at least they used to.
Also, that guide would be able to fill in all but any unknown repeaters. Not
so much with coordinates, but at least a location.

Tam, WB2TT wrote:
"One would not expect somebody to measure an antenna at a height of 3 feet."

For reception of nearby broadcast stations a wire at 3 feet above the earth is probably fine but the wire would have a low radiation resistance.

The radiation resistance of a 1/2-wave dipole versus its height above ground in wavelengths is probably a familiar graph for many. It starts at zero ohms at zero height and rises in an almost straight inclined line to about 99 ohms at nearly 5/8-wavelength. Then, with increased height, the radiation resistance oscillates as a damped wave around 73 ohms.

Forgive me for being a completely ignorant novice, but I built a simple ground plane antenna which seemed to cure my directional broadcast problems (broadcasting over my yard), but I unplugged it for a while, and now when I try to broadcast the signal is very weak, and doesn't change even though I unplugged the antenna. In other words, I was listening to the broadcast right at the Ramsey FM10a transmitter, and when I unplugged the antenna cable, the signal didn't change. Am I right in thinking that the coax connection to the antenna is broken somewhere and that the transmission is coming completely from the antenna jack of the transmitter?

Thanks for your help.

Thank You One and All for your Replies.

Well I have the two Inverted "L" Antennas and the proof would
be in the Doing by de-rigging one and wrapping the Antenna Wire
around a Ferrite Core; so that the Coil will be at the Top of
Vertical Up-Leg. Then doing some Side-by-Side Testing of the
two Antennas.

NOTE: Taking a second look at the RF Systems "EMF" Antenna.
The more I get the impression that it is susposed to be Rigged
as a Vertical using the Coax Cable as a Counterpoise or may be
as an Inverted "L" with the Coax Cable as the Vertical Up-Leg
and the Antenna as the Horizontal Out-Arm.

once again thank you very much one and all ~ RHF

J.S. Snpw wrote:
"---I unplugged the antenna cable, the signal didn`t change."

You need to measure carrier level to determine FM signal strength. Once the "FM improvement threshold" signal is reached, very little increase in audio level results from increases in RF. It`s the magic which makes RF repeaters work well. All signals, weak and strong, are nearly as strong in audio levels.

Next. If you build kits, you probably have a way to test continuity. Check your antenna circuit for opens and shorts in all the right and wrong places.

Best regards, Richard Harrison, KB5WZI

>amateur stations altogether.

There is no requirement at all for amateur repeaters to be registered with the FCC, and as far as I know they do not make any attempt to maintain such a database. The FCC stopped requiring registration of amateur station locations, in most cases, some decades ago.

The best information you're likely to find would be from your local repeater frequency coordination council or organization. See the ARRL's page at http://www.arrl.org/nfcc/coordinators.htm to find your coordinator.

There's a couple of further gotchas, though. Many repeaters are not coordinated (there's no legal requirement that they be coordinated, as long as they aren't interfering with other repeaters), and many repeater owners are reluctant to publish the actual location of their repeater sites (for fear of vandalism or theft, I suspect).

You can find some information about repeaters on the ArtSci Publications page at www.artscipub.com/repeaters/, and the ARRL has a repeater directory and, I think, a version on CD-ROM. As far as detailed coverage analysis goes, though, I suspect that neither will have the detailed latitude/longitude/altitude information you'd need to do any sort of high-definition coverage maps in areas with hills.

Yes. My response was intentionally simplified. Making a directional antenna is often not a viable option for an SWL, because they typically operate over a wide frequency range, and want to receive signals from many directions. This pretty much limits them to something like a rotatable log periodic antenna. Wire antennas can be made directional, but typically only in fixed or a small number of directions, and with directional patterns that change with frequency. Within the range of discussion, then, I don't believe it's realistic to attempt a directional antenna. The advertised antenna certainly doesn't produce any advantage in this regard.

I like to put up a big hi gain FM broadcast band antenna (by big I mean 15 - 20 feet).

I can get the formulas for the spacing of the reflectors and directors from literature, but it always says further optimization will be necessary.

This 'further optimization' might prove difficult and I wonder if anybody here has experience with this or has built one of these antennas??

Having no adjustments, and presumably no 62 Ohm coax, you must have bent it into a V to get 50 Ohms. If you put a parasitic element on it, it is not a dipole.

It's a decent enough antenna but the real marketing hype lies in the
claim that those three lame whiskers which protrude from the base of
the thing act as "decoupling sections". Which don't work worth a hill
of beans in their advertised role *particularly* with this antenna
which is notorious for tossing RF back into le shack. The way to
actually clean up a Ringo II and get it cooking properly is to install
an RF choke wound, beaded or otherwise near the feedpoint.

Bill, I was taken aback by your somewhat harsh response and I hope you are not speaking for everybody, but just for yourself.

What, in your opinion, does not qualify in my question, the fact that I am not allowed to transmit on the frequency I wish to receive??

The physical laws are the same, be it for a 6m antenna, for example, or a FM broadcast receiving antenna. In fact I was thinking in stripping my Cushcraft 13 element 2 m antenna for the purpose and just lengthen all the elements.

I hope others will be more inclined to share what they know.

1.5 wavelengths is about 15 feet near the center of the FM broadcast band. Kraus gives an example of this 6-element Yagi. It has a radiator, reflector, and 4 directors in Fig. 8-29 on page 248 of his 3rd edition of "Antennas". Directivity is about 12 dBi and bandwidth is 10%. Construction is not too critical because the space between its elements is fairly wide.

I have built Yagis and been pleased with their performance.

I'll bet I can get good reliable converage to a 100 miles with a 5
watt HT and a rubber duck with todays receivers.
50 to 75 mile coverage to mobiles.

It's worked on 52 simplex every time I've tried it.
Fasten the belt clip to the strap above the arm rest with the rubber
duck sticking straight up into the big window, Hook a boom mike and
ear piece to the HT and put my ANR head set over it.
Call CQ and darn near get a pile up.

Ain't nothing like a good tall antenna.

I think Richard has hit the nail on the head. I wish calculation of electromagnetic fields could be reduced to a simple equation. Any undergraduate text on electromagnetics barely scratches the surface. I suggest you check the site at www.nec2.org and download the .pdf version of the "NEC Program Description -- Theory". Gives an overview of "Method of Moments". As a foundation Kraus' Electromagnetics may help, and is available used (and cheap) at www.bn.com. Also at the same site a reprint of "Field Computation by Moment Methods" by Roger F. Harrington can be obtained for $33.50. Then there is the "Finite Element" method as used by "Ansoft's" HFSS".

Regards,

Frank

Hi Uwe

I'd suspect that the optimisation you are talking about is not going to make a lot of difference to your end use. You tend to be able to tune yagi's for best forward gain or best front to back ratio but not both together. You have the added complication that if you want to cover the entire FM band a single yagi would be a major compromise and it might be better looking into a different kind of design like a log periodic or axial mode helix.

As a general rule too, the longer the yagi the narrower bandwidth its operation is. My gut feel for a 20ft FM band yagi antenna would be only for use over maybe 200kHz. It would of course still work further from the design frequency but at reduced performance.

As an aside some of the optimisation will be due to slight material differences and deviations from original mounting techniques (eg through boom vs on top, proximity to buildings etc)

Would you care to share you reasons for the high gain design? Is it one distant station you want or just for general DX use? Might you be trying to reduce interference effects?

Cheers Bob VK2YQA

So do I...

Just for giggles, what gain
> does Witchcraft claim?

I'm sure too much....:/ They always did tend to lean to funky gain
numbers, and references for verticals...In the real world, the RR2 is
considered slightly inferior to the dual 5/8 isopole, which claimed a
fairly realistic 3 dbd if I remember right. And they don't claim the
lower decoupling cone on the isopole is a 3rd element either. Also,
the element lengths on the RR2 are a little off from the normal dual
5/8.. I think thats one reason for the "odd" length of the phasing
stub. It is a fairly decent antenna though for the price. The lower
decoupling section did help the antenna a lot. But I don't really
consider the 50 inch coax section above the radials a 3rd radiating
element. If I'm thinking this right, if that was the case, it would be
out of phase with the lower actual element...?? Or it would
seem..There is no phasing stub between the coax section, and the lower
element. Just the matching device. One tidbit...I found a simple well
decoupled 1/4 wave GP with the tip at the same height as the tip of
the RR2 is nearly equal to the RR2..Pretty close anyway. MK

Uwe,

Check out www.cebik.com he has an article "some notes on FM BC
antennas". Or at least something like that. He does extensive
antenna modeling.

One of the problwms with FB broadcast antennas is that 88-108 (US FM
allocation) is a very wide band percentage wise to make a good yagi
for. Programs like YO, QY4, are likely inadaquate for wide
bandwidth antennas so you may end uo with EzNEC or one of the
NEC varient calculation programs for antenna design.

If you were to take a 13b2 and lengthen the elements they would be too
closely space to get the same performace as the origional. You have
to scale length, spacing (and boom length) and diameter by the same
factor to get the same antenna at a different frequency. IE:
everything would be about 1.45 larger to optimize for 100Mhz.

Good luck.
Allison

It would probably be a poor idea to modify the 2M antenna. As someone else mentioned, your spacing would not be correct.

A 15 foot long boom would support 1 Reflector, 1 Driven Element, and 5 Director elements. This would give you a estimated gain of almost 10 dBd. Normally the bandwidth of these antennas is about 7% at the design frequency. For your use this would be about 6.5 MHz. If you are only interested in a small portion of the band, this will work fine.

Getting higher gains is a case of diminishing returns. Typically, to obtain a 3 db increase in gain you need to double the number of director elements and effectively double the boom length. So, going from 15 to 20 feet will only gain you another 1 or 2 db. In cases of extreme fringe operation, this may make a difference, but mostly you won't notice it. If you want to play with boom lengths and element spacing try one of my web pages at:

http://www.k7mem.com/Electronic_Notebook/antennas/yagi_vhf.html

Optimization is nice to do if you have the equipment, but with careful construction, you should be able to build a antenna that is very close to the intended specifications and not require any tedious tweaking.

For other antenna designs you might try Ian White's (G3SEK) web site at:

http://www.ifwtech.co.uk/g3sek/diy-yagi

If your intent is to cover the entire FM band, you may want to look for information on Log-Periodic antennas. Gain will not be big, but the bandwidth will be.

# 2323. Amateur Radio Elmers Resource Directory

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-16 14:08:05 UTC
From: "Paul W. Schleck" <pschleck@novia.net>
Message-ID: <419a091d$0$9373$45beb828@newscene.com>
Source record: 86620
Cross-posted to:
rec.radio.amateur.misc,rec.radio.amateur.antenna,rec.radio.amateur.digital.misc,rec.radio.amateur.homebrew,rec.radio.info

The Amateur Radio Elmers Resource Directory, a list of experts, mentors, and gurus for amateur radio on the Internet, went on indefinite hiatus on June 1, 2000 after just over 9 years of service. This decision was not forced upon me by anyone for any particular legal or technical reason. Rather, I decided to retire from maintenance to focus on other personal and professional interests and obligations.

I also felt that I had taken this project to the limit of my expertise and spare time in terms of format, visibility, automation of maintenance, effective recruiting, and even good Web design. It's clear that the Internet had changed greatly over the 9 years that the Directory had been in existence. The Directory had evolved from a flat text file edited on a VAX running VMS to a well-featured Web site. However, in that time, much better amateur radio-related web sites had emerged (including QRZ, Ham Radio Online, and ARRL) that make my site rather simplistic by comparison. Also, it's clear that many more enhancements would be required to make the Directory more maintainable and secure. One requirement that the Directory did not address is reasonably shielding the Elmers from having their E-mail addresses harvested for junk-mail distribution lists.

I want to emphasize that I do believe that using the Internet, the Usenet Newsgroups, and the World-Wide Web to bring Elmers and amateurs requiring assistance together continues to be worthwhile. Because of this, I would consider a highly-qualified and motivated volunteer to take it over immediately. The Directory consisted of a moderate number of large text files, scripts, and other configuration files. It's neatly arranged, and can probably be easily transplanted to another Unix/Linux environment. I would also be willing to assist with importing the data into a database such as mySQL. To help transition this project to another maintainer, I had prepared a maintainer's guide, available on request. The ideal candidate will be a motivated self-starter and self-teacher possessing several years of experience in:

- Unix/Linux
- C or Java
- HTML
- Perl or Python
- Procmail
- Version control systems such as SCCS, RCS, CVS, etc.

(this also implies that you have the above tools installed in your environment)

preferably on or more of the following:

- SQL
- PHP
- CSS

and have approximately 4-6 hours of spare time per month for maintenance. A track history of successfully completing projects would be a firm requirement. Please note that hosting sites are already available. Offers to host the project, but not maintain it, are not being sought at this time.

Familiarity with news.answers formatting conventions and the auto-faq FAQ Management and Posting Package would be a plus. Concrete proposals for enhancing the Directory to be a top-10 amateur-radio-related Web site would also be desirable. I would also consider the Directory being incorporated into an existing commercial amateur-radio-related Web site as long as the essential non-commercial character of the Directory was maintained.

If you feel that you possess the interest, motivation, and immediate, hit-the-ground-running, skill set to do this, please send your statement of interest and any proposals you wish to make regarding your plans for future enhancements to elmers-request@novia.net.

I would like to thank all of the volunteer Elmers, as well as courteous users of the Directory, for making this service a success, as well as an enjoyable experience for me over 9 years.

Bob, the reason to want the high gain is as follows.

I live in Maine south of the Canadian border, close but not quite close enough to receive Canadian FM stations. I can receive one station faintly using a Radio Shack BC band antenna and wanted to expand on that with a better antenna and possibly a change in IF filters in the tuner I use.

And I thought that a very high gain antenna with its narrow pattern would also aide in adjacent channel rejection. I realize that it could be a problem covering the entire BC band and I am not set on any particular design, I first wanted to see what people here had to say.

Curious John wrote:
"Can someone please provide a correct near field equation that I can understand?"

The relation between the current in a wire and the magnetic field intensity (H) around it at any distance (r) is:

H = 2I / r
I is the current in a long straight wire.

The magnetomotive force around a complete contour around a wire is: 4Pi (I)

If the current is changing, the magnetic field is likewise changing. An electric field is induced in the space around the wire. The voltage induced in a wire properly immersed in the field is:

-d Phi /dt

The induced voltage is proportional to the rate of change of the magnetic flux and is negative, that is it opposes the changing flux.

When an electric field is imposed on a dielectric, it places an electrical strain in the dielectric. This causes a dielectric displacement current (D):

D = dielectric constant x volts/m of the electric field. So D is equivalent to an electric flux density. Displacement current is greater in materials with larger values of dielectric constant. The value for air or space is one.

Best regards, Richard Harrison, KB5WZI

Kraus` 6-element Yagi on page 248 of the 3rd edition of "Antennas" has 12 dBi doirectivity and a 10% bandwidth. FM channels are 200 KHz wide. 10% of 100 MHz is 10 MHz. That is 50x what you need for a single channel.

If you want to cover the entire FM band with an antenna, you can do it easily with a rhombic. Arnold B. Bailey`s rhombic in "TV and Other Receiving Antennas" scales to: two #10 wires 72 feet long, separated by 36 feet at the midpoint. Overall length is 61 feet. Surge resistance is 600 ohms, and 600 ohms is used as the terminating resistor value. Bailey uses 300-ohm twinlead as a transmission line. Gain is 14.5 dBd (or less). Bandwidth is 30% for 1 dB down. That`s 1.5x the width (20 MHz) of the U.S. FM band.

What you probably need is height. Signal drops fast in the shadow of the horizon or an obstruction.

Best regards, Richard Harrison, KB5WZI

John Snow wrote:
"Now I need to address hum."

It is likely the FM kit is 100% solid-state. Filament wiring and leakage are out of the question.

Shielding is necessary on low-level, high-impedance audio wiring. Continuity of shields and their supposed connections is mandatory.

Low ripple is needed in the d-c power supply. The placement of the supply and its components must be isolated so that these do not induce a-c into sensitive circuits.

Ground connections within the FM circuit must be sequenced and arranged so that a low-level circuit is not sharing the ground return of a high-level circuit. This imposes high-level noise (hum) in the low-level circuit. This is sometimes called a ground loop.

I recall solving the phono oscillator hum problem just by putting enough distance between the oscillator and the receiver.

Best regards, Richard Harrison, KB5WZI

I don't think you want horizontal polarization for a repeater- everyone
(except ATV) I am familiar with is vertically polarized.

Hi Uwe

I cant resist... Brrrr COLD! I visited Toronto early this year and havent gotten over the throat irritation yet! It was about 33C when I left Sydney and -25C when I got to Toronto!

Well then I can now see the use of employing the narrowest band design possible, assuming you only want the Canadian station. Personally I wouldnt want to limit its bandwidth because I *might* one day want to use it for another distant station.

Is it worthwhile doing an analysis of those stations that might interfere? Like if the interfering source is at 90 degrees heading from the station you want, anything that starts as a dipole element will help. If its directly behind you may want to adjust for best front to back, even to the point of tuning the reflector with some C. This BTW is much easier on a quad reflector than a yagi. (ie make a "Qagi")

My theoru isnt good on this, but I can see you want a design that has got low sidelobes and good front to back. Yagis can be optimised for all manner of things so one design you see may work great for f/b but bad in sidelobes. Is a phased array better? (ie mount your boom at right angles to the station and use 2 element designs) How does a quad or helix compare? Does choosing circular polarisation help? This is actually a more difficult problem than first thought.

My path would be not to think too much, but put up a helix and see how it performs. I use to have one on 2M for satellite work that I also used for terrestrial TV and FM. (Very wide band) I was however in a zero interference area. Given though that I guess you want to go with a yagi design, my thought is to build it to the Canadian station frequency with a tuned refelector and also see what happens. When you have built it plot the pattern at various frequencies. Have a look at Mr Cebiks web page on OWA yagi's. (http://www.cebik.com/2mowa1.html) He often shows radiation patterns and lots of other data. Well worth a look.

Apologies for the length!

Cheers Bob VK2YQA

Uwe,

I suspect you can buy a commercially made FM antenna for the cost of materials that it would cost to build your own (excluding the rhombic). Optimization is nor very practical unless you want to spends 100's of $$$ on test equipment. The large Radio Shack FM antenna, if they still make it, should do the job. An ANTENNA MOUNTED preamp might also help. Since you are trying to pick up distant stations, antenna height is very important.

"Looking to build a decent 6 mtr antenna... probably a loop... Space no problem indoor or out..."

I suppose vertical polarization is used in the repeater you would like to reach 50 miles away, so that it is compatible with mobiles.

Hopefully your repeater antenna is at high altitude on a TV tower or some such lofty perch. You need about 1250 feet of elevation to provide a horizon 50 miles away.

Height of the station antenna on your end reduces the repeater antenna height required. A vertical loop antenna is fed in the middle of a vertical side and makes an array of two 1/4-wave vertical dipoles, separated in space by 1/4-wave. It has slightly more gain in the direction of the plane of the vertical sides. The ground quality surrounding the antenna affects its performance but radials are not worthwhile.
There is a slight gain versus a groundplane antenna.

In free space, the radiation resistance of a square quad loop of one wavelength circumference is about 120 ohms. It would work best with balanced feed.

ON4UN`s "Low-Band DXing" has a chapter "Large Loop Antennas" which would likely be worth a look.

Best regards, Richard Harrison, KB5WZI

Beta Users and advanced features Sign-up here...
http://www.eigensearch.com/inc/constructs/betasignup.htm

Central to eigenSearch Advanced is the freedom to construct complex search explorations, save the forms for later use; and apply weight factor to each phrase and term. EigenSearch processing will apply eigenvector math and Jacobian matrices to construct search terms that are tailored to your exploration. Cross-pollination is also applied as described below. The eigenvector approach is clearly highly advanced and would normally be useful for very sophisticated applications. Nevertheless, anyone may utilize the method. An advanced form is simply a matrix in which the user types words and phrases randomly in a multi-cell form (please click thumbnail to view).

Advanced features

EigenOperator (cross pollination) and eigenvector constructs
Cross document content pollination within every web site directory tree (unlike conventional search engines and tools eigenSearch checks for your terms and phrases and drills down though multiple directory documents)
EigenSearch cross-pollination is applied to documents within the same (tree) level in a URL (peer documents). Thereby limiting the amount of contamination of results
Illustration:
"Blood Hounds" + "English Breed" will present documents that contain either of these phrases within the same peer level in a document storage structure; for example, within the directory: www.smartdogs/hounds.
eigenSearch limits pollinating occurrences outside a peer level. For example; "blood hounds" + "English breed" found in two different directories would not report an eigenSearch result: i.e. "Blood hounds" found in www.smartdogs/hounds and "English Breed" found in. www.smartdogs/hounds/Europe would not be found. EigenSearch therefore searches

one tree (peer) level in a site and looks for multiple occurrences of multiple phrases across all documents within this peer level.
Corporate products can be tailored to drill down infinite levels for eigenOperator (cross-pollinating operator) matching.
eigenSearch single phrase results will find all documents and show the results as independent findings. This way the user can find results across many documents and the combined highly constrained results are reserved for a single level cross pollination. Extremely high (cross-pollinating) eigenValues will correspond to finely granular and refined search explorations.

Beta users receive the following features:
Login and password
Save search constructs for later use in your own personal construct tables
EigenOperator (cross Pollinating Operator) advanced features as described above (eigenvector to follow)
Database (Table) upload and eigenvector computations
EigenSearch seeks 300,000 beta testers for its advanced eigenOperator based cognitive engine. This engine will allow for a multiplicity of search parameters for users to select so as to mathematically narrow results. The system will employ eigenVectors, eigenValues and eigenMatrices to determine relevance to user searches; thereby rendering high fidelity confirmed search results.
Naturally the computational power for doing such math is why beta testers are required. Each tester is welcome to comment on user friendliness, speed, change and ergonomic elegance. It is an eigenSearch goal to continue advancing the user interface so as to remain intuitively simple to use while at the same time providing hi-fidelity explorations. All beta testers will receive a login and password, which provides entry into features for saving search constructs and parameters according to their own classification approach. Saved results and parameters can be used at any time and modified to alter search results. Beta users will be able to import their own data sets (2-dimentional) and perform an eigenValue analysis.

Depends on how high the repeater antenna is and how much power you're
running -- to hit a repeater at that distance your best bet is
probably a small beam, regardless of polarization issues.

A beam would also be your best bet for general 6 meter work.

Six meter beams aren't all that expensive -- if you really want to
homebrew one, do a google search.

# 2338. New Program - Coaxial Choke

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-16 22:57:03 UTC
From: Reg Edwards <g4fgq.regp@ZZZbtinternet.com>
Message-ID: <cne0jv$2iv$1@hercules.btinternet.com>
Source record: 86534

```
New program SELFRES2.exe
-------------------------------------
Input data :

Length and diameter of solenoid.
Number of turns.
Conductor diameter
Length of line in which the coil is inserted.
Testing frequency.

Output data :

Coil self-capacitance.
Coil self-resonant frequency.
Choke impedance vs frequency.
Insertion loss of choke in dB.

Performance is based on a choke wound with coaxial cable of the same type as
the transmission transmission line in which it is inserted. Conductor
diameter is that of the coax outer. It behaves a single wire. Coax inner
diameter is of no consequence.

Choke insertion loss is a measure of the reduction in power radiated from
the feedline. But, despite the attention it attracts, actual power radiated
from the feedline WITH the choke will never be known because the power
radiated WITHOUT the choke is indeterminate.

SELFRES2 is 51 K-bytes. Download from website below in a few seconds. It is
not zipped-up and will run immediately.

# 2341. Re: 6 mtr antenna help( Antenna Cross Polarization)

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-16 23:40:38 UTC
From: Keyboard In The Wilderness <Key@Kennel.net>
Message-ID: <Wdwmd.145329$hj.99955@fed1read07>
Source record: 86537

From URL:
http://www.astronantennas.com/polarization.html

On line-of-sight (LOS) paths, it is most important that the polarization of the antennas at both ends of the path use the same polarization. In a linearly polarized system, a misalignment of polarization of 45 degrees will degrade the signal up to 3 dB and if misaligned 90 degrees the attenuation can be 20 dB or more.

==========

The line-of-sight performance on a 50 mile path, at 50 MHz, with a Tx power of 50 watts and similarly polarised half-wave dipoles, is approx as follows -

Tx to Rx transmission loss = 100 dB.
50-ohm Rx input volts = 500 micro-volts.
Equivalent to S9 + 20 dB.

Which is a very loud signal level.

However, due to Earth curvature, at 50 MHz the radio horizon at ground level is only about 14 miles. And as Richard says, at least one of the Tx and Rx antennas must be elevated to more than 1250 feet above the other to achieve a line-of-sight condition without any high ground obstructions in between.

Attenuation beyond the horizon increases rapidly due to diffraction. But you might just about make it with 50 watts and a 3-element vertical antenna. (A dipole with 1 reflector + 1 director.) (Or a dipole + 2 directors.) (Or you could try just 1 director.) Expect some fading depending on weather conditions.

On the other hand, if you were lucky when you chose your QTH, you may come booming through. Enjoy yourself experimenting with a vertical antenna as high as possible above the roof tops.

>What to do when the propagation is not in your favor:<

Heh...when I was a kid, my father got 100' of tower from a local radio station...I dug the hole (6' deep 4' wide...such fun) and we mounted the guyed tower on it. As I was the only one who could handle "altitude w/o airspeed" I got to mount the rotor, mast and antennas. Was sitting on top of the tower (after drilling the mounting holes for the homebrew thrust bearing) in easy sight of the local highway, when I heard the screech of tires. A local truck driver saw me on the tower and thought I was going to jump! He apparently called a couple of buddies on his CB as two other trucks showed up a few minutes later. Guess they were disappointed when I pulled the 21' mast up and started installing it.....

Darn, wish I had A) a similar tower and B) a place to put it!! My XYL would have a fit, but what a signal~~~

Having no record of who said what, or what the discussion was about, someone may be interested in little program INV_VEE which, amongst other things, demonstrates how the feedpoint impedance of an inverted-V dipole varies with the enclosed angle from 0 to 180 degrees for any height above ground.

Download INV_VEE from website below.

Your main aim with this antenna - is to get it as HIGH as you can and use
good feedline
Use a 5/8-wave vertical - or a quad (side fed)

The main thing with the antenna is being able the "hear" the repeater, so as
long as his power equals or exceeds the repeater's power, if he can hear it,
he can use it.

There is a 10 foot boom KLM driven element style yagi in the YO yagi
collection supplied with the program that is 75 ohms and claims 20%
bandwidth. I'm sure there are several here that could supply that
design, or run it again with more boom and elements. Or possibly
someone could run it under AO with more than 3 optimization frequencies,
which may be more desirable yet.

hi,

I am taking a trip on a dive boat to Cocos Island off of Costa Rica.
I'm thinking about trying to bring an HF rig. What suggestions have
you for an antenna? It would have to fit into a reasonably "standard"
suitcase, or go as carry-on luggage, since packing space is limited.

Reg, please could you make the terminating impedance a user variable too? (There's space for just one more parameter.) That would allow choke performance to be calculated for the standard test conditions of 50 ohms source and 50 ohms termination.

Real-life source and load impedances are, as you say, indeterminate (or largely so). However, there still needs to be a standard test environment for comparing published data for different chokes, and comparing predictions against measurements. 50-50 meets that need.

Well, I did it. I changed plans at the last second, though,
going for the Hustler CG-144 monobander with radial kit.
Instead of paying $200 for the GP-9, I paid $27 and got
almost as much gain.

After figuring my old antenna's gain - coax - connectors, I
figured the new coax (Flexi 4XL) and antenna. The new

antenna is 5 feet higher and my system gained 3.940 db.

My S-meter on my 2 meter rig is stingy, esp. around S8
where it has an almost logritmic scale action. Still, several
repeaters went from S3 to S5 and several went from S7
to S9. One repeater remained S1 but it's noise factor went
from 50% quieting to 70% quieting.

Turns out it probably was a good decision - the Hustler
has 5.2 dbi gain and the tip is at 42'. I'm just stating to get
intermod at this level of performance (I live between a
hospital & Boeing). I'm convinced if I had gone with the
GP-9, I would have serious intermod problems (plus my
wallet would be $170 lighter) plus raising it would have
been MUCH harder.

Thanks to all who offered advice on this topic - You guys
rule!

Take a look at the www.njqrp.org/pac-12 website. I built one of these and
have been very happy with it. The wire ground radials may prove to be a
problem, but the idea might be worth considering. I've used it while camping.

"What suggestions have you for an antenna?"

Avoid the sharks off Cocos Island.

From a boat at sea, you have a perfect earth connection available. Dunk an electrode and use it for HF. If the boat is metal, just make a ground connection outside to the hull. HF won`t penetrate the metal. Then use a vertical wire as an antenna. The sea short-circuits horizontal polarization. L-antennas are often used on boats. The horizontal portion is just capacitive loading for the real antenna which is the vertical portion. Loaded vertical whips are another type of common boat antenna.

Best regards, Richard Harrison, KB5WZI

Tony,

Not too many people use 6m FM, but on SSB, If both ends are running 50W to a 6 element beam at 50 feet, the probability of being able to work out to 100 miles is essentially 100%.

Bob, K5QWG wrote:
"dunno know how big your boat is, but possibly a "tape-measure" dipole:"

A Go-Tenna is collapsible for easy packing, but twice as long as an equivalent monopole, used against the sea, a near perfect ground.

A Go-Tenna can be deployed as a vertical and so could be effective at sea but requires twice the altitude of an equivalent monopole.

Horizontal deployment requires an elevation of a couple of wavelengths at sea to be very effective. That`s usually excessive.

Recall that the ground wave is vertically polarized. There is no horizontally polarized wave propagation over the sea.

Terman says on page 808 of his 1955 edition:
"Examination of these vector diagrams show that with s perfect reflectoe the horizontal components of the electric field will exactly cancel each other at the surface of the perfect reflector. In contrast the vertical components of the electric field of the incident and reflected waves do not cancel, but rather add at the reflector surface with small values of Psi 2 (the vertical takeoff angle from the surface)."

Source record: 86564

I apologize if this post is slightly off-topic for this group, but I'm pretty sure you're the right crowd for the question...

I'm trying to connect a Yagi antenna to an old 915MHz WaveLAN wireless access point (circa 1997). I have searched high and low, but cannot figure out what type of connector I need. Since a picture is worth a thousand words, I've taken the liberty of providing some visual aid! Here is a picture of the mystery connector I'm hoping to identify:

http://kd7ump.ftml.net/WaveLANAntennaConnector.jpg

Now, this looks suspiciously like an SMB connector. Alas, it is not. I had a custom pigtail cable made (for $38!) using an SMB connector and it is not a match. Here is a picture of the mystery connector and the SMB connector side-by-side:

http://kd7ump.ftml.net/WaveLAN-SMB.jpg

Close, but no go :( If anyone has an idea what this might be (or has some other clever idea on how to get from the access point to a RP-TNC connector) please, please let me know! And if you can cc: me via email as well, that'd be swell - I don't want to miss your response.

http://www.gb3fh.org.uk/

this is the repeater guys...

its not so far away but I was hopeing to get a few more on 6....
there are,n many over here but Europe would hopefully pop up some times
with propagation....

I can only run 10 watts as I am an M3.....

So thats why I thought about a loop for some gain...

like the look on a "cactus" too....

I can get in to the repeater now with a long wire and tuner but wanted a
dedicated antenna for the chance of DX and other repeaters should a lift
rise...

Thanks for the great replies and good luck.....

This is channel 2 land. Essentially no 6 m FM. Why don't you try a simple
vertical first, and figure out how much more gain you are going to need, if
any. I just mentioned the SSB figures to show that you don't need to have
your antenna at 1000 feet.

# 2376. Colinear 2 meter antenna question

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-17 19:40:30 UTC
From: Ken Bessler <kg0wx@NOSPAMyahoo.com>
Message-ID: <lONmd.1172$3I.850@okepread01>
Source record: 86473

I'm using the Hustler CG-144 colinear antenna
with the radial kit. The antenna is 42' above
ground and fed with 35' of Flexi 4XL coax.

This antenna is apparantly a 1/4 wave phased into
a 5/8 wave and is working well.

My question is what impedance (SWR) would
this antenna sho on 446 mhz? I don't have a 440
mobile but I do have a VX-2R HT and I hooked
it up on 440 to this antenna and it seemed to
perform well.

Source record: 86476

Hi John

Thats a very open ended question!

You can use a 2M antenna half a metre off the ground. It wont however be very effective in distance covered!

My view would be to mount an antenna at the maximum permissible height and ensure that the coax run used was low enough loss. What I am getting at here is dont run more than (say) 5 metres of RG58. Use something lower loss like RG213. (I cant really be specific)

All this of course depends on what you are trying to achieve. If you want to use only a few local repeaters it may be possible to get away with a low mounted antenna. If however you want long distance simplex contacts, height is important. If you want to input to FM satellites, height isnt such a problem as antenna type is (it needs to radiate upwards to some degree)

What are your interests and what type of antenna are you going to use?

Cheers Bob VK2YQA

John Hurkett wrote:
"What would be the minimum height that I could use?"

Distance to your radio horizon in miles equals the square root of twice the antenna height in feet.

Suppose your antenna is up 50 feet. The square root of 100 is 10 miles.

Between two antennas at 50 feet each, the line of sight path length is 20 miles over smooth earth.

An antenna disguised as a flagpole can actually be a coaxial antenna.

Ken Bessler wrote:
"My question is what impedance (SWR) would this antenna show on 446 MHz?"

An antenna operating on its 3rd harmonic may be roughly a 1/4-wave connected to the drivepoint through an additional 1/2-wavelength of antenna.

The 1/2-wave portion repeats the impedance it "sees" at its ends, therefore the drivepoint "sees"the same impedance that the length in excess of 1/2-wavelength presents. If this is a good match to the drivepoint, as it well may be, you will have a low SWR.

Best regards, Richard Harrison, KB5WZI

446/3 = 148.7 so a 2m antenna will often resonate on 440 MHz.
The trouble usually is a high radiation angle on 3x the
fundamental frequency for ordinary verticals. How the above
antenna would radiate on 446 MHz is an educated guess. My
guess is at a very high radiation angle. But if it hits the
repeater you want to hit, it's "working".

Ian,

Done!

It took 7 hours including updating program notes, local records, website, making backups, notifying customers and writing this message. I spent an hour testing for and removing a dozen or so bugs inevitably introduced by modifications more involved than you perhaps realise. Normally this takes a week or two but its only a hank of cable and a residual bug won't amount to very much. ;o)

It added about 1.5 K-bytes to the source code. It has improved the screen's appearance. The extra facility will add to a user's interest in a choke's behaviour.

Thanks very much for your suggestion.

I changed the program's name. Download SELFRES3 now.

On the suggestion of Ian White, G3SEK, program SELFRES2 has been modified by the addition of an extra operating facility.

The terminating impedance at the other end of the line from the coaxial choke, which was fixed at 20 ohms, can now be varied between 1ohm and 1000 ohms from the keyboard.

The name has been changed to SELFRES3 and is now available from website below. If you have already downloaded the earlier version which is no longer available, overwrite it with SELFRES3.

The worth it question seems to be that you spent $ 27 for a net gain to get one repeater to go from about 50% to 70 % quieting. The other repeaters were peobably full quieting so you would not gain anything on them even if you spent the full $ 200. Whe 'worth it " will come when you are making contacts that you did not make with what you already had.

Hi, Greg.

Thanks for your reply. I did get a reply back from Cable Xperts who theorized that it might be a QMA connector. They don't carry QMA connectors anymore, but I found a picture of a QMA plug on Amphenol's site and it isn't the right one :(

Anyone else have an idea?

Well, N0IDW can hear me on simplex at 40 miles away now
where he only heard silence before. The real performance factor
will kick in during the next band opening.

Also, a fringe repeater is now within range (60 miles away) and I
can use it's signal to check for band openings.

Simon - it appears you may have antenna height and antenna length confused.
(your subject refers to length and your post refers to height)
Minimum height you can use is probably "ground level" - or - zero feet
in other words - as long as you can hear the other station - you can
probably talk to it.

Are you saying that my low (less than 1/2 wavelength high) horizontal antenna will be next to useless if I live on the sea shore? And that same antenna will perform much better if I live inland where soil conditions are poor?

Kevin:

It is an "inverted" SMB. The FCC mandated non-standard connectors on wireless stuff to prevent casual tinkerers from
sticking yagis on them. Thus came "inverted" BNC, TNC, SMA, SMB, and a bunch of others with a female center pin in a
male body and vice- versa. Try Pasternack.

Source record: 86493

Hi All

I will be moving to a house early next year that has 90ft trees scattered around the backyard. Rather than setup a tower (initially anyway) I am looking at hanging a wire (1/2" braid) 2 metre collinear for a rope between the trees and feeding it from the bottom end.

Firstly talking about phasing sections. Has anyone come accross the maths/size of using a single turn of stiff wire (looks like a ring match) to go between the elements? Was thinking a short length of PVC pipe with dowel or fibreglass spacers. How big?

What is the general figure of merit for shortening the topmost element by when joined to a (say) PVC insulator.

And feeding. Was thinking about the J pole type match - The two parallel wires 1/4 wavelenth long and a direct coax feed a few inches from the bottom. Are there any better end/voltage fed methods?

Any thoughts or other construction methods/ideas appreciated.

Cheers Bob VK2YQA

Gary, K4FMX wrote:
"Are you saying that my low (less than 1/2 wavelength high) horizontal antenna will be next to useless if I live on the sea shore?"

No. Your antenna will do whatever it does. I said that sea water reflects so well that the reflected ray from the sea is almost as strong as the incident ray. At low angles they cancel when horizontally polarized, being equal and of opposite polarity, and this eliminates low-angle radiation. This is demonstrated in Figs. 13 & 14 on page 3-12 of the 19th edition of the "ARRL Antenna Book".

Low horizontal wires tend to send most energy straight up. This can provide near vertical incidence contacts.

For distance, when the reflecting surface is good (sea water) and the antenna is low, the antenna had better be placed vertically. Results are shown in Fig 16 on page 3-13 of the same book.

Chuck wrote:
"Or that only vertically polarized signals can be intercepted by ships at sea?"

I served on a navy ship in WW-2. Our antenna was a low-L. It could intercept either polarity but responded only to line of sight and high-angle signals. This was a deliberate design. The Navy did not want our emissions QRM-ing the world. Our range was limited to about 500 miles. We could contact our shore destinations at about 2 days travel from them (our ship was slow).

The description for the radiation patterns say they are over flat ground. Would the patterns be similar over water?

Hello Richard,

I think Gary and I were taking issue with your statement:

"Recall that the ground wave is vertically polarized. There is no
horizontally polarized wave propagation over the sea."

While the first sentence is correct, the second would be a bit of
surprise if it were true. Indeed, your experience on the naval vessel
utilized horizontal propagation over the sea. But it is not correct to
equate horizontal polarization with low-angle polarization.

I think I understand what you meant to say.

73,

Chuck

To me, your connector looks like a "Mini 75 Ohm SMB" plug.

I have a connector catalog in front of me from Pasternack Enterprises,
but without exact dimensions, it's difficult to be sure.

Try http://www.pasternack.com or send them email at sales@pasternack.com

Their web site should have some phone numbers as well.

Chuck wrote:
"While the first sentence is correct, the second would be a bit of a surprise if true."

Terman writes on page 803 of his 1955 edition:
"The ground wave is vertically polarized, because any horizontal component of electric field in contact with the earth is short-circuited by the earth."

On page 808 of the same book:
"Examination of the vector diagrams shows that with a perfect reflector (read sea water) the horizontal components of electric field will exactly cancel each other at the surface of the perfect reflector. In contrast, the vertical components of the electric field of the incident and reflected waves do not cancel, but rather add at the reflector surface with (small values of elevation angle from the surface) Psi.

It`s true. Terman has been tested for 7 decades.

No, but at some distance from the water, its benefits fade away. I`ve read, and I don`t remember where, that the benefit of high conductivity only extends 1 or 2 blocks back from the water`s edge and then it is gone.

More money is spent on Viagra and breast implants than on Alzheimer`s research. With aging baby boomers, we may soon have crowds of salient people who don`t know why.

This could be a little misleading.

Horizontal antennas perform just about the same over salt water as they do over regular ground, with one exception: If the horizontal antenna is low, very high angle waves will be attenuated when over real ground, but won't be attenuated nearly as much if over sea water. The radiation at zero elevation angle is zero for any antenna height and ground conductivity. So there's nothing about sea water that would make a horizontal antenna work worse than over ground.

However, a vertically polarized antenna has much stronger low angle radiation when over sea water (*) than when over plain ground. And this low angle radiation can be much stronger than anything but a very high horizontal antenna. So a vertically polarized antenna is usually the best choice for a boat.

I also don't think that an L antenna is the best idea, especially if the horizontal part is low. If it is, the horizontal portion radiates mostly straight up, wasting part of your power. It's a better idea to make a T shaped antenna. Then the top will radiate very little, leaving most of the radiation to the vertical section.

(*) The important factor for good low angle radiation is the ground conductivity at the point where reflection occurs, rather than the conductivity just under the antenna. For lower and lower angles, the reflection occurs at farther and farther distances from the antenna. Also, the reflection occurs farther away as the antenna gets higher. For typical HF antennas and low angle propagation, the important region is on the order of up to a few hundred feet from the antenna. Efficiency is a separate issue, and for that, the important thing is the conductivity just under and close to the antenna. Having the antenna directly over salt water makes getting a good low loss ground connection easy, as another poster pointed out.

Allow me post a couple of formulae ?? formulas ??
How about equations?

Balanis 2 Ed. p 32-33
Reactive near field -> .62 * A
where A = Square Root of (D^3)/lambda
D= length of a Hertzian dipole (both elements)
lambda is the wavelength of a transmitting frequency
radiating near field -> 2*(D^2)/lambda
Outside of that is the far field.
This is area that you seem concerned about.
Krauss uses Reactive near field as inside lamda/(2 * pie)

Do you work for a group of physicists? I have encountered the
field equations from a physics text by Young and Friedman.

Source record: 86507

Here's an interesting website:

http://micro.magnet.fsu.edu/primer/java/interference/waveinteractions/

Destructive and constructive interference can be explored
using a javascript application. What is asserted at the
bottom of the page is particularly interesting:

"In addition, when two waves of equal amplitude and wavelength
that are 180-degrees (half a wavelength) out of phase with each
other meet, they are not actually annihilated, as suggested in
Figure 1. All of the photon energy present in these waves must
somehow be recovered or redistributed in a new direction, according
to the law of energy conservation (photons are not capable of self-
annihilation). Instead, upon meeting, the photons are redistributed
to regions that permit constructive interference, so the effect should
be considered as a redistribution of light waves and photon energy
rather than the spontaneous construction or destruction of light.
Therefore, simple diagrams, such as the one illustrated in Figure 1,
should only be considered as tools that assist with the calculation of
light energy traveling *in a specific direction*." i.e. if Figure 1
didn't ignore reflections, there would be wave(s) traveling off in
some other direction(s).

Translating this to the match point in a transmission line with
reflections: Destructive interference between two reflected waves
cause the elimination of reflections toward the source in a matched
system. "All of the photon energy present in these (canceled) waves
must somehow be recovered or redistributed in a new direction, ..."

There's only one other direction in a transmission line and that's
back toward the load. When the reflected energy is re-reflected
(redistributed) at a match point, it is simply following the existing
laws of EM physics.

Moreover, the point being missed by the original correspondent (one which is obvious from this and other descriptions of the phenomena), is that no _energy_ is transferred in the direction of totally destructive interfering waves - a point which I have made repeatedly on this newsgroup, and which he has steadfastly refused to accept. The observation that the energy in question must go elsewhere remains obvious.

Richard Clark wrote:
"I would suggest you research the "Franklin Array"."

Current reverses at the open-circuit end of an antenna. 180-degrees back from the open end it reverses again. Current flowing in opposite directions begins to reduce the field strength perpendicular to the antenna when the total length reaches 5/8-wavelength.

At a point 1/2-wave or 5/8-wave back from the open circuit, a phase inverter is used to produce (2) mostly in-phase antenna segments. Some ways to get in-phase segments are to drive the array at that point. Or, to connect the segments through a short-circuit 1/4-wave stub. The "Super-J Maritime Antenna" in the ARRL Antenna Book uses this method. Or, use a lumped network in place of the short-circuit stub.

Kraus shows an interesting and simple phase inverter in Figure 23-21(b) on page 824 of his 3rd edition of "Antennas". The inverters are self-resonant coils. No external capacitors required. They are "traps".

The Melles-Groit web page says: "In the absence of absorption or scatter,
the principle of conservation of energy indicates all "lost" reflected
intensity will appear as enhanced intensity in the transmitted beam."

This is in regards to a thin-film anti-glare coating. If a laser beam
is perpendicular to the plane of the thin-film, the reflected beam
and the transmitted beam will lie in a STRAIGHT LINE. Where did you
get the idea that it has to be "orthogonal to the direction of
propagation"?

>>There's only one other direction in a transmission line and that's
>>back toward the load.
>
> This does not follow from the other.

Sure it does. There are only two directions possible in a transmission
line and if energy traveling toward the source is "redistributed in a
new direction", there exists only one other direction available, i.e.
toward the load.

> newsgroup, and which he has steadfastly refused to accept.

You know that's a false statement, one of many you have made about
my postings.

Of course, no energy is transferred past the match point in the
direction of totally destructive interfering waves. DUUUHHHHHH,
THAT'S WHY THE REFLECTED POWER METER READS ZERO ON THE SOURCE
SIDE OF THE MATCH POINT, DUUUHHHHHH. And that's why the reflected
energy traveling toward the source on the load side of the match
point gets redistributed in the only other available direction,
i.e. re-reflected back toward the load.

What I said was: For two reflected waves to cancel, they must
first exist even if for only an infinitesimally small amount of
time. Since you disagree with that, it means the reflected waves
never existed. And if, as you say, they never existed, how could
they possibly cancel? You seem to have invented a new phenomena -
two waves canceling without the waves ever existing.

> Extremely low conductivity would produce radiation as in free space;
> no cancellation in the horizontal plane.

No, that's not true. The radiation at zero elevation angle is zero for any antenna height and ground conductivity, even "extremely low".

Sometimes it's necessary to look beyond simplified quotes read in books, and read and understand the underlying math. In this case, the math can be found as equation 1(*) on p. 717 of Kraus' _Antennas_, 2nd Ed. (I thought this was also in the 1st Ed., but can't find it there.) This is the equation for reflection coefficient from ground for horizontal polarization. It's easily seen that it equals -1 at an elevation angle (alpha) = 0 for any value of ground conductivity or permittivity. (Note that epsilon-sub-r is the complex permittivity, as shown in eq. 4(**), which contains the conductivity.) The total field is given in equation 3(***), which shows that its value is zero when the elevation angle is zero and the reflection coefficient is -1.

This is, however, entirely theoretical. As the elevation angle gets lower and lower, the reflection point becomes farther and farther from the antenna. So a reflection at zero elevation angle takes place at an infinite distance from the antenna. Among other problems, this requires an observation point an infinite distance away and a perfectly flat ground plane that's infinite in extent. While this is the standard for a lot of theoretical analysis and in programs like NEC, MININEC, and EZNEC, it of course can't be constructed in reality. In real life, the Earth curves away, so if the terrain is perfectly flat, extremely low angle radiation never strikes the ground. (Without working through the numbers, I'd guess this to be below a small fraction of a degree for a moderate antenna height. But it would be easy to calculate.) Again theorectically, still using a simple reflection model but now with an idealized model of a spherical ground, you'd get a free space pattern at zero elevation angle and up to a fraction of a degree *regardless of the ground conductivity*. But when slicing things this thin, you probably need to use a better reflection model, which takes into account dispersion and refraction. I'm not sure how that would modify the result.

(*) rho(horiz) = (er*sin(a) - sqrt(er - cos^2(a))) / (er*sin(a) +
sqrt(er - cos^2(a))) where

er = epsilon-sub-r = (complex) relative permittivity of the ground
a = alpha = elevation angle

(**) er = er' - j * sigma/(omega * e0) where

er' = epsilon-sub-r prime = (DC) dielectric constant of the ground
sigma = ground conductivity
omega = radian frequency = 2 * pi * f
e0 = permittivity of free space

(***) E(horiz) = 1 + rho(horiz) * [cos(2*Bh*sin(a) + j*sin(2*Bh*sin(a)]
where

B = beta = 2 * pi / wavelength
h = height of horizontal antenna above ground
a = alpha = elevation angle

Kevin -

It looks like a bit like reverse TNC. There were some proprietary
connectors and Lucent used the Proprietary ORiNOCO on many of their
products (late 1990s), Lucent and Orinoco used the same cards for some
models. Cross reference a connector known as: SMZ

Drop an e-mail to Fab Corp., and tell them exact model you have -- they
should be able to cross reference.

I have three ground rods each about 30 inches from a leg of my tower. I want to connect about 40 radials to the tower. It would be much easier to connect the radials to the ground rods and then have a single connection from each ground rod to the base of the tower. My interest in 160 meters - 30 meters. Is there a problem with this?

I am using #2 battery cables from the ground rods to the tower base. These have a nice clamp on one end; with a copper shim the clamp works on the ground rod. The other end has a lug that fits between a pair of ss washers that are compressed by an extra 1" nut on the concrete bolts of the tower base. (I will try to seal this area to keep excessive water from it.) (It is a small tower in an area not very lightning prone.)

In almost 45 years of ham operation I have never bothered with a "good" ground connection. I am in what might be my last location and now have a "real" tower (55' crank up). I understand the principles behind a single ground, or at least I think I do. However, ideal requirements (as often quoted in various codes and standards manuals) need to be matched with what one can actually do.

I have several ground rods by the tower and one by the entry to my basement shack. The tower-to-entry-point has two #10 wires in the trench (but not not in the conduit) that connect the nearest of the tower ground rods to the entry-point rod. The distance is about 45'.

From the entry point area to the rig is about 10' and has a single #10 wire. Also from the rig area to the electrical panel is another #10 wire that is about 40'.

Is this a reasonable arrangement? Is it better than nothing? Worse than nothing?

I will shortly place two ICE units at the entry point on the two coax lines from the tower. I am still considering what to do with the control lines --- there are 12 for a SteppIR, 6 for a rotator, and 6 for a remote coax switch.

I believe the proper response is "non sequitur", i.e.
your response makes no sense at all. If your orthogonal
responses are not "beams of photons", pray tell, exactly
what are they?

Hi Bill, it's reasonable and better than most, providing the following is
also true:

The coax shields grounded at the tower (min. at the bottom, best top and
bottom), and again at the basement entrance single point ground. Shields
must be grounded before connection to an arrestor.

> I will shortly place two ICE units at the entry point on the two coax
lines

ICE also makes protection for control lines. I have no experience with them
in particular, but my six ICE coax arrestors have handled a lot of surge
from several strikes less than 100' away, two of which were within 50' of
antennas.

I would also add that the importance of the bonding between shack single
point ground and AC service entry point ground is critical to prevent ground
potential rise (GPR) from a nearby strike's energy from going through your
equipment via your own ground connections. The path in from ground and out
through the back of your equipment AC power cords will always exist, but
with proper bonding it will not be a destructive connection. Most stations
have this station-ground to mains-ground bonding conductor outside the
station, but I don't see the harm of having it inside either *if* it was a

very short distance [yours is NOT SHORT]. The shorter the route for this bond the better, whatever path it may take. NEC requires it be less than 20'. Fat chance you say. Alternatives are to provide multiple ground rods along a >20' path of this critical bond. That means change your bonding conductor to run outside, from the station single point ground (rod), via a couple additional rods, to the AC mains service entry ground (rod).

Bill,

I would reroute the wire from your electrical panel directly to the ground rod just outside your entry. Then from there run a single line to your rig. This keeps the rig out of the middle of the ground connections. If possible your AC line for the rig should run from where that ground rod is. AC protectors should be put at that point along with the coax protectors. Now you have a single point ground system and the rig is not in the middle of things. All grounds are at one point including all your protectors.

As far as the control wires, get some large MOV's and place one on each line to ground. Again at your single ground point where your ground rod is at the entrance.

With several control lines any surge energy that comes down them will be shared by all. You can get by without gas tubes in this situation as all those MOV's are effectively in parallel.

If you look inside a rotator protector like Polyphaser makes that is all you will find in them.

The ground connection from your protection devices to your ground rod should be as short and as large as you can manage. 3" wide copper strap if the distance is a few feet. If it is a little longer run place two copper straps edge to edge in parallel or a 6" strap.

It is important to have a low resistance / low inductance path to your ground system. In addition you may want to add more ground rods / radials to your entrance ground. Even just buried radials run out in different directions away from that single ground rod that you have will help lots. Placing an additional ground rod at the end of each is still better. The big thing is to run the radials in different directions to get some space between your ground rods. Ideally the distance between rods should be the sum of their lengths.
The ground saturates when trying to dissipate energy in one place. Spreading it out increases the amount of energy you can dump in a given amount of time.

Roy, W7EL wrote:
"No, that`s not true. The radiation at zero elevation angle is zero for any antenna height and ground conductivity, even "extremely low"."

We need no simplified quotes nor formulas. Reflection requires a "discontinuity". The resistance of free space is 377 ohms. As long as a traveling wave in space encounters 377 ohms, its velocity and trajectory are not altered.

"Extremely low" could include a soil that for practical purposes appears to the wave as 377 ohms. Surely the earth could be absorbent and not highly reflective. In that case, the reflected wave reaching a distant observer or antenna would come practically from the incident wave alone.

377-ohm earth may be hard to come by. Sheets impregnated with carbon were invnted by Winfield Salisbury at the Harvard Radio Research Laboratory during WW-2. These cloth sheets are patented and are called Salisbury sheets.

A similar technique was contemporaneously developed in Germany by J. Jaumann.

So it`s not likely to just happen upon completely non-reflective soil. But, surely most soil absorbs some energy from the wave striking it. So, the reflection from the soil will be weakened and will be unequal to the task of completely canceling the incident wave. Cancellation at zero degrees will be incomplete.

Hi Dave:

By inspection, both of your equations show that the units of the solution will be in meters. E field strength units are in V/m, and in the near field, will be complex numbers. From memory, I believe your expression for the near field/far field transition is correct. I do not have my own copy of Balanis, but will check it when I get a chance.

Even for a non-realizable "Hertzian dipole", where the current is assumed to be constant along its entire length, the math is fairly involved. Not sure if a physics text is the best source for antenna studies. By what I have read; Young and Friedman's texts have not had very good reviews -- by students anyway!

No, I do not work for physicists. Most of the time I have worked in EE labs. Electromagnetics is more of a hobby for me. So far I have been using undergraduate texts, such as Paul and Nasar's "Introduction to Electromagnetic fields". The problem with this book is that there are no answers in the back.

I was running a cgt-144 and when I got a dual band mobile I used it on
440. The swr was higher than I liked so I added an adjustable grounded
vertical element about a 1/4 wave long about 1.5" away from the
CGT-144. The idea was to turn it into an open stub j-pole on 440. I
was able to get the swr below 2:1 on the repeater input freqs and in
theory the 1/4 wave 2m section (3/4 on 440) would radiate as an end
fed 1/2 wave on 440. It didn't seem to hurt the 2m operation at all.
It didn't work as well on 440 as the dual band Comet CA-2x4SR that I'm
using now but it did work.

I'm also planning on using the CG-144 with radials as fixed station
antenna now that it's been retired from mobile service.

Do you ever give a straight answer? I gave you a laser example.
There are no responses orthogonal to the main beam. Everything,
including reflections and reflected wave cancellation, happens
in a straight line with the laser beam according to the Melles-
Groit web page where they say: " In the absence of absorption or
scatter, the principle of conservation of energy indicates all
"lost" reflected intensity will appear as enhanced intensity in
the transmitted beam." *ALL* intensity is contained in the
transmitted beam in the absence of absorption or scatter.

Jack - regarding your comment on grounding the shields BEFORE connection to an arrestor: My arrestors are mounted on the common ground panel and the coax is grounded via the coax connector to those arrestors. What is the reason for a separate ground prior to that one. Maybe I misunderstood something, but it seems redundant to have a separate ground a few inches from that one.

In response to another's comments regarding protection of the SteppIR, rotor, and other control lines: I use MOVs and .01 bypass caps on all those lines in a box at the base of the tower and have another set of the same at the entry panel box. Those components are mounted via European-style screw terminal strips (12 positions per strip) obtained from Jameco via the Web. Much cheaper than the same from Radio Shack or other sources. MOVs came from Mouser. A lightning strike last year entered my shack via relay control lines which were unprotected at that time. Hopefully, the new arrangement will help.

It would be too much of a coincidence for 'a', the attenuation factor, to be the same whether in series or in shunt. Most of the attenuation at HF is due to I^2*R losses, a series event.

Transmission lines are distributed networks involved with EM wave energy transmission. I^2*R losses can cause a decrease in current just as it can cause a decrease in voltage. The sequence of events is obvious.

1. The RF voltage drops because of I^2*R losses.
2. The proportional E-field decreases because of the voltage drop.
3. Since the E-field to H-field ratio is fixed by Z0, the H-field decreases as does the ExH power in the wave.
4. Since the RF current is proportional to the H-field, the current decreases by the same percentage as the voltage.

The chain of cause and effect is obvious. The current decreases because of I^2*R losses in the transmission line which is a distributed network, not a circuit.

Bob,

I don't know about the 5/8, but you are basically on the right track. I once bought an Andrew 1900 MHz vertical that claimed 8 or 10 dbi gain, non directional. It had multiple radiators stacked vertically inside a plastic tube about 1/2 inch OD, couple of feet tall. No idea how it was phased internally, but don't think it had any coils in there. I had it mounted via an N connector on top of a metal box, but don't think it required a ground plane.

Apparently I should have added that distributed resistive losses in
series create distributed voltage drops with a common current through
all, but distributed resistive losses in shunt create a distribution of
Norton current sources, where the shunt current on the transmission line
or radiator at a given point is the sum of all equivalent current
sources between that point and the end of the transmission line/radiator.

Distributed shunt resistive losses would imply dielectric losses
which certainly exist but are minimum at HF. We could even assume
a worst case open-wire transmission line made from resistance wire
and located in the vacuum of free space. There doesn't seem to be
any valid way to justify asserting that shunt losses exactly equal
series losses in every possible transmission line at every possible
frequency under every possible conditions. Asserting such is just
an admission that one it trying to force reality to match the math
model rather than vice versa.

In a flat transmission line without reflections, if the E-field
drops, the characteristic impedance of the transmission line
forces energy to migrate from the H-field to the E-field, such
that the constant V/I ratio remains equal to Z0. Thus, the H-field
supplies energy to compensate for the losses in the E-field.

> from that one.

Coax shield grounding must be accomplished at the tower top, tower base (on ground level, not even 6" above!) and before the arrestor to comply with protector manufacturer requirements and to be in keeping with best engineering practices that are used nationwide in communication tower designs. The grounding just before the arrestor is for two purposes: 1. preventing unnecessary energy (whether capacitively or inductively coupled) from challenging the gas tube, MOV, coil (or all three) mechanisms of a protector, and 2: to help limit the differing potential available to reverse-path voltage from a nearby strike in ground potential rise conditions. A nearby strike can saturate the ground system, and a station ground can reference hundreds of thousands of volts 'up' from the ground, and 'out' via arrestors, phone, power cables to lower potential felt at some distant point. Grounding cable shield at the station single point ground thus helps maintain equipotential for both directions. Even if the station coax arrestors are mounted on the master ground the additional grounding is still helpful for voltage-division during saturated ground conditions. But in all cases that ground bus mount must never be the only place the coax shelding is grounded!

Several amateurs have reported successful use of private design MOV on control lines. While this could exceed commercially available equipment specs in some cases, for those less familiar with such designs, they are readily available in package-form to protect control lines.

Jack

Don't forget, as always happens, that when Zo is assumed to be purely resistive, as is always done, it automatically forces wire resistance loss to equal shunt conductance loss. You've lost a degree of freedom. Which has a considerable bearing on your arguments.

Reg, seems I learned back in the dark ages that if Z0 is assumed to
be purely resistive, it forces wire resistance loss to equal shunt
conductance loss - AND BOTH OF THEM ARE EQUAL TO ZERO, i.e. the
line is lossless.

Actually, the argument is not about lossless lines, but about lines
with an attenuation factor term. I'm assuming that when Z0 is not
purely resistive, the ratio of voltage to current still equals a
constant Z0. If the E-field is attenuated by series I^2*R losses,
the H-field will supply energy to the E-field in an amount that will
maintain the Z0 constant ratio. If the H-field is attenuated by shunt
I^2*R losses, the E-field will supply energy to the H-field in an
amount that will maintain the Z0 constant ratio. That's why the
attenuation factors are identical - there's simply no other alternative.

Cecil,

I am curious how you separate "reality" from the "math model". I have never directly measured the properties of open-wire transmission lines located in the vacuum of free space. Have you?

How do you know that "reality" is correct and the "math model" is wrong?

The second paragraph is even more curious. Do you have a reference for this migration of energy from the H-field to supply the suffering E-field? I must have missed that day in class.

73,
Gene

Floyd,

The real reason for grounding the coax shield at the entrance panel in
addition to having the protection device grounded is the voltage drop
between the connector and the coax line. The cable to connector
connection is usually not a good low resistance - high current joint
as far as lightning is considered. During a lightning strike you may
have considerable voltage drop across that junction.
Sometimes connectors are found to have been welded to the cable or
their threads welded due to lightning strikes because of the poor
connection at the connector. Other times the junction may get burned
open.

It can also melt the solder quickly in a soldered on connector which would provide for an immediately poor connection.
However, lots of people do not do the extra grounding of the cable at that point. Most are lucky if they get some sort of protection device installed and a ground connected.

As Jack mentioned grounding the cable "at the bottom of the tower like is used nation wide in tower designs" is ideal. But unfortunately that is not how it usually gets done. Often the lines come off the tower at 6 to 10 feet above the ground to go to the building in a cable tray. But it would indeed be best if they were taken all the way to ground level before exiting the tower.

The reason being that during a strike the tower and associated lines on it develop considerable voltage drop due to the high current being conducted. Coming off the tower above ground is like taping a resistor part way up from the ground end. Allowing more voltage to exit on the lines rather than the potential at the base of the tower where it is closer to ground. The tower usually has considerable inductance for voltage to develop across.

Ideally lines should be grounded to the tower not only at the top and bottom but at distances along the tower length as well. This is to avoid flashovers that may puncture the line.

Lightning protection schemes are all about voltage drop. Most due to inductance of the tower or other conductors carrying the current. All conductors will have inductance and resistance and therefore voltage drop if they are asked to carry lightning current. Keeping things out of the middle of that path is the trick.

==========

Dear Cec,

You ought to have more sense than try to argue with ME about transmission
lines. You had better return to the dark-ages before Heaviside and start
again from square one.

If I say, when Zo is made purely resistive, that Series Resistance and Shunt
Conductance losses automatically become equal to each other even when
NEITHER is zero, then I really do mean "When Zo is made purely resistive,
Series Resistance and Shunt Conductance losses automatically become equal to
each other even when NEITHER is zero."

So your argument, whatever it is, falls as flat as a pancake on Good Friday.

With a ridiculous question like that, I rest my case! Reality is
*always* correct. If the math model disagrees with reality, it is
simply wrong! Do you really think that what happens only in your
mind is reality? As my Mother once said, "If that's what you think,
think again!"

Example: The 19th century math model didn't explain the orbit of
Mercury. Do you think you can control the orbit of Mercury in
your mind? I suppose in your world, you really can do that.

> The second paragraph is even more curious. Do you have a reference for
> this migration of energy from the H-field to supply the suffering
> E-field? I must have missed that day in class.

You were probably out with a cold that day in kindergarten. It's
called "conservation of energy". If the ratio of the E-field to
the H-field is a constant, any change in either one will result
in a change in the other. This is a well known and accepted fact
of physics in the field of optics. How did you miss it? Hint: What
happens to isotropic radiation in 3D space? Both the E-field and
H-field decrease in value per square meter and THEIR RATIO STAYS
EXACTLY THE SAME.

FYI, the characteristic impedance or index of refraction forces the
ratio of the E-field to the H-field to a constant value. When a
forward wave in a 50 ohm transmission line encounters a 50 ohm
to 300 ohm impedance discontinuity, the ratio of the voltage to
current in the forward wave changes from 50 to 300. I'm extremely
surprised that you don't know and don't accept that fact of physics.

==========

Cec, I assume you know the simple formula for Zo from R,L,G,C.

Write it down. It will then be obvious, to make the angle of Zo equal to
zero it is necessary only that the angle of R+j*Omega*L be made equal to the
angle of G+j*Omega*C.

Or even more simple, for Zo to be purely resistive, G = C*R/L

If R and G exist, as they always do, then the line cannot be lossless.

We have all the math we need to handle Pluto's orbit, and have had for a century. We do not, however, know all the bits out there that may perturb it. That said, we can still predict it quite well enough for anyone's current needs.

Hi Tom,

Exactly, but you were responding to a dry comment on the nature of
"reality vs. models" which was absurd from the get-go.

To say that reality drives models or vice-versa (especially from
armchair theorists) is naive in the extreme. Anyone's "knowledge" of
reality is simply its own corrupt model and not any particular state
of enlightenment. The naive part is in not knowing the errors
bounding this "knowledge."

Barring revolution, anarchy, social upset or the rest, futurity will
tend generally to more resolution in the answer and a finer reduction
of error, but it will never be fully resolved because the answer could
not be encompassed by the mind.

Cecil,

You nicely ducked the question, again.

This is not about philosophy, existentialism, the meaning of life, planetary orbits, or any other such fluff.

Again, how do you know the "reality" for your transmission line in free space?

This is a straightforward question. Do you have data? Do you have a reference that you consider reality? Are you basing your reality on a model? Is it just a matter of blind faith? Something else?

You have many times made similar remarks about us "stupid folks" who get misled by math models. How do you get your information?

As for the E- and H-fields, this just gets more amusing by the minute.

73,
Gene

Adding to Richard's comments, many antenna tuners have a built-in 4:1 Balun in them, some only make this available on certain settings. A 4:1 Balun at the feedpoint of a 70-80' random wire will typically match very easily (on a tuner of course) from 160 meters through 40 meters or above. You can additionally, mount the Balun on the top 12" of an 8' ground rod, and ground one of the two Balun outputs to the ground rod, connecting the other to the wire as a feed. This is one of my very effective antennas, and quiet even in a highly populated area. Industrial Communication Engineers (ICE) also makes a nice matching device with adjustable impedance setpoints where their Balun is automatically grounded and provides lightning protection as well. That device is however for receive-only.

Reg, there is no contradiction between what I have said and what you have said.

Continuing the discussion - For average transmission lines used on HF
frequencies, "... the value of G ... is likely to be too small to affect the
attenuation factor ..." Quote from "Transmission Lines" by Chipman, page 94.

Some of Chipman's calculations indicate that, for a typical 10 MHz example,
R is about 0.1 ohm/meter while G is about 0.9 micromhos/meter. That's about
a 100,000:1 ratio making G negligible as far as attenuation factor goes.

The attenuation factor depends almost entirely on R, the series resistance
parameter. G, the parallel conductance parameter, has a negligible effect
on the attenuation factor at HF.

Since, at HF, the attenuation factor consists almost entirely of series
resistance, and since the attenuation factor is identical for voltage and
current, it logically follows that the series resistance is primarily
responsible for the attenuation of the current.

> Or even more simple, for Zo to be purely resistive, G = C*R/L

Actually, that is only an approximation for low-loss lines.

Simple, we know the characteristics of copper wire and we know the
dielectric properties of a vacuum. Examples abound in textbooks.

> This is a straightforward question. Do you have data?

Of course, don't you? If not, maybe you had better get some.

> You have many times made similar remarks about us "stupid folks" who get
> misled by math models. How do you get your information?

The distributed network model was developed because the circuit model
failed in systems that are an appreciable portion of a wavelength. I'm
surprised that you don't have that information.

> As for the E- and H-fields, this just gets more amusing by the minute.

The attenuation factor for the average transmission line at HF is almost
entirely due to the resistance in the conductors as the shunt conductance
is usually negligible. Resistance in the conductors causes a voltage drop.
Yet, we know that the current is attenuated by exactly the same percentage
as the voltage. Since G is negligible, R must be responsible for the
decrease in current. What laws of physics can account for that fact?

Z0 determines the ratio of HF voltage to HF current. Therefore, if the
voltage drops and the V/I ratio stays constant, energy must be transferred
from the H-field to the E-field. That's pretty simple stuff, Gene, maybe
sophomore level.

Sorry, I should have said (effect of R) >> (effect of G)
on the losses. Or 0.1 ohms/meter in series has a greater
effect than 1/(0.9 micromhos/meter) in parallel. That's
about 7 magnitudes difference based on an example in
"Transmission Lines" by Chipman.

Reg Edwards wrote:
> Or even more simple, for Zo to be purely resistive, G = C*R/L

In "Transmission Lines" by Chipman, he gives an example where R = 0.1 ohm/m and G = 0.9 micromhos/m. For Z0 to be a purely resistive 50 ohms, G would have to be 40 micromhos/m making the transmission line considerably more lossy just to achieve a purely resistive Z0. Real world transmission lines rarely have a purely resistive characteristic impedance.

The formula for the attenuation factor is R/2*Z0 + G*Z0/2
That's 0.001 + 0.0000225, so you can see that G has negligible effect on losses, i.e. virtually all losses in the above example are series I^2*R losses.

The attenuation factor is 0.0010225 for both the voltage and current so it's obvious that the current attenuation is caused by the series I^2*R losses, the same thing that causes the voltage attenuation.

Hi Bob, are you familiar with http://www.si-list.org/swindex2.html ? There is a link on this site for Linux executable NEC2 source code, which I believe has been translated from FORTRAN to C. Will not help you with the Windows emulator, but it seems you will be able to run NEC2 at least.

Regards,

Frank

Great stuff, Cecil!
You raise and intersting point. I had not considered my call as confusing
but am wondering what my CQ's will generate in responses.

I am sorting out some radio issue here and hope to be sending on HF very
soon.

Thanks.

Russ KG6TDX

I have not made any contacts on cw yet other than the few I have set up in
advance with another local ham on 2 meters. I was planning on working HF
this weekend, but my Icom 706 G is not transmitting on the HF
bands--scratching my head...

Dee,
I do have a preliminary HF station set up, but my 706 G is not transmitting on HF for some reason. My 80-meter dipole is tuned to flat SWR but no luck. I bought the radio new last January and have never transmitted on HF (obviously). The last time I used 6-meters, it worked fine. It may be warranty time...

I have other old radios in the closet: Johnson Valiant, Heathkit DX 40 and RME 4350 receiver, but these need some tech time before putting them on the air.

Thanks for the congrats! I feel like an 8 year old kid with a brand new bicycle!

>>> for this migration of energy from the H-field to supply the suffering
>>> E-field?

Here's the reference: From "Fields and Waves" by Ramo and Whinnery.
Take a close look at the exponential transmission line equations
for flat lines (no reflections):

V = Vmax(e^-az)(e^wt-bz) (1)

I = Vmax(e^-az)(e^wt-bz)/Z0 (2)

'a' (alpha) is the attenuation factor. The two equations are identical
except for the Z0 term. If you divide equation (1) by equation (2),
you get Z0. In a flat transmission line (no reflections) the current
is ALWAYS equal to the voltage divided by the characteristic impedance
of the transmission line. The voltage and current are attenuated by
EXACTLY the same factor. If the voltage drops because of I^2*R losses,
the current must decrease by exactly the same percentage. (I have avoided
calling it a current drop so it wouldn't upset you.)

Since the attenuation factor is R/2*Z0 + G*Z0/2 and since, for most
transmission lines used on HF, R/2*Z0 >> G*Z0/2, the current attenuation
is caused by the series I^2*R drop in the voltage and the V/I=Z0 ratio
that must be maintained - pretty simple logic.

>>> I must have missed that day in class.

Yep, you must have. But it's not too late to learn what you missed
that day. :-)

You expect me to remember the exact wording after 40 years?
Perhaps your prof, like mine, told you to skip sections 1.22-
1.28 in Ramo and Whinnery. I didn't take his advice - I read
them.

So Gene, please point out the error in my logic. If the
current attenuation is primarily from R, the series
resistance, what other explanation can there be than
energy is being supplied by the H-field to the sagging
E-field? Can you think of any other rational, logical,
non-emotional, technical explanation, given these
exponential transmission line equations?

V = Vmax(e^-az)*e^j(wt-bz)

I = Vmax(e^-az)*e^j(wt-bz)/Z0

V/I = Z0

(I think you are just trying to punish me for saying my
dog has a soul. :-)

See if you can get a more experienced ham to come over and help you. It could simply be that you don't have something set right. We all pulled that stunt a time or two or dozen. I've been a ham for 12 years (Extra class) and just this past Field Day I sat down to take my turn at the radio, switched to CW, and nothing happened when I tried to transmit. It turns out that I forgot to set the radio for break-in keying. My only excuse was that I wasn't used to that radio but I should have checked.

Source record: 86399

I accidentally found your discussion. Having nothing else better to do I thought I would make the following remarks -

The 9:1 balun on a 'long wire', on the average, has no effect on what you call the antenna 'effectiveness'. On receive, you may find the signal strength marginally better at some random frequencies and marginally worse at other random frequencies.

4:1 baluns have a similar negligible effect at different sets of random frequencies with a very slightly smaller overall loss over the whole wide band from MF to HF.

You may just as well omit a balun altogether. Omission of a balun means zero balun loss. But loss in a balun is negligible anyway. It just means there is nothing to be gained by fitting one.

Baluns can be useful in particular frequency bands. But if you are interested in particular bands then a very simple tuned antenna, a coil or capacitor, or changing antenna length, is much to be preferred.

Baluns in a receiving application are beneficial only to the bank-balances of balun manufacturers and salesmen. In other words, don't waste you hard-earned money!

(PS: The supposed 600-ohm Zo of a random length of wire has very little to do with it. Concentrate on the exact particular antenna length. Please send me the money you save.)

And forgive me for the interruption.

Depending on length, height and wire diameter, Zo can vary between 450 and 650 ohms or thereabouts. What's yours?

Then what balun ratio would the guru's and old wives recommend? And to confuse even further, receivers can have an input impedance anywhere between 50 and 1000 ohms.

Some tuned receivers have an indeterminate input impedance. Who needs a balun?

Well Reg need and want are two different things. Perhaps my inverted
L didn't 'need' a balun, however after installing an ICE-182A
DC-Isolated matching transformer (balun if you will) I had a
noticeable reduction in noise. The difference is real and as a result
I have a better S/N ratio that makes listening less fatiguing. Now
here's the $64,000 question ........."Was the difference due to
impedance matching, the DC isolation or did a previously un-noticed
loose ground get fixed when I put the ICE unit in-line?"

Howard

You know Howard, it's mostly amateur radio operators who have read too much
and worked too little that make statements like "a balun for receiving is
just for the balun makers benefit". These hams have little idea how
hobbyists who have special interest in DX, especially utility, and have
tried and tested numerous receiver antenna systems over the years. As I said
earlier I too use ICE equipment on one receive-only antenna. I could care
less what a stuffed-shirt thinks that does for my receive ability, as I used
it first as a hobbyist and then professionally. It certainly does improves
my digital and analog signal reception. I have that Ice box impedance set to
favor the lower bands on the wire and it at times outperforms a matched
dipole in reception. The compromise is that I lose usefulness of that wire
much above 6 mhz,which is ok as it does it required job superfluously. Now

the 4:1 current-type balun use on another wire-set antenna provides quiet listening as well as excellent transmit abilities from 2182 Khz through 11000 Khz. And of course I use a 1:1 current-balun on a long dipole. Would I "have" to? Of course not. Does it improve the antennas abilities in listening as well as transmit? You bet it does. Do what works for you and God help anyone who argues with that.

Hi Bob, I guessed you would have been familiar with that site, but thought I would mention it just in case. I have never used 4NEC2, but understand it is just like real NEC2 where you enter data on the NEC "Cards". Most of the time I use NEC-Win Pro, which is very easy to use, and you also have full access to all the cards. It also has the Sommerfeld/Norton feature built in.

Regards,

Frank

I'm one of those who pulls the coax off the tower at around eight feet
and hangs it on a carrier wire from the tower to the outside wall near
the shack. In the past I've had end insulators at both ends of the
carrier wire. Your point about grounding the coax at the base of the
tower is well taken but is obviously not possible in these situations.
It occurs to me that the same effect can be accomplished by connecting
a #6 or #8 solid wire between the the coax shields where they bend
away from the tower and the base of the tower. Yes?

Taking it a bit further it also occurs to me that the carrier wire
could be connected to the base of the tower at the point where the
tower connects to the ground rods there, then up the tower and
connected to both the coax shields at the eight foot level and the
tower again. Then horizontally to the house wall with the coax, then
down to the ground rods just outside the shack to which the equipment
is also grounded. I'd also connect the coax shields to the carrier
wire again at the point where they turn away from the wire and go
through the wall. One hefty continuous, unbroken length of copper
wire. There would still be voltage differentials involved because
there is no escape from the inductances BUT . . . is my thinking in
the right direction here?

Wunnerful! another gem from The Reg. I took the revised version out
for a couple test drives and it's very nice. As usual.

However I have an ongoing problem of a very practical nature involving
how to "wind" a true solenoid from coaxial cable. Turns out that at
the moment I'm pondering how to build as lightweight as possible
chokes made from RG-58 coax for 30, 20 and 2M dipoles. Does anybody

around here know how to fabricate a proper coax solenoid without having to resort to some beastly heavy coil form like PVC pipe? How do ya wind one which holds its shape out in the WX without a coil form? Is there some magic goop out there which can bond the turns together or what?

Theref are many installations like yours in existance. It was the
"common way" to do it some years ago. Not the best though.

>In the past I've had end insulators at both ends of the
>carrier wire. Your point about grounding the coax at the base of the

>away from the tower and the base of the tower. Yes?

No that won't do much good. If you ground the coax shield to the tower
where it bends away from the tower you will have a much better (lower
inductance) to ground with the tower than what the wire would provide.
The wire would do almost no good at all when compared to the much
larger tower in parallel.

>
>Taking it a bit further it also occurs to me that the carrier wire
>could be connected to the base of the tower at the point where the
>tower connects to the ground rods there, then up the tower and

>connected to both the coax shields at the eight foot level and the
>tower again.

Same as above. Grounding the carrier to the tower will do much more
than a wire to the ground rods at the tower. The carrier wire should
not be insulated from the tower. It and the coax should both be
grounded to the tower at the exit point. Otherwise you can have
flashover's to the carrier.

>Then horizontally to the house wall with the coax, then
>down to the ground rods just outside the shack to which the equipment
>is also grounded. I'd also connect the coax shields to the carrier
>wire again at the point where they turn away from the wire and go

>there is no escape from the inductances BUT . . . is my thinking in
>the right direction here?

Connecting the carrier wire to the coax again at the house is a good
idea for the same reason you should connect it at the tower. to
prevent flashovers to the cables. The same situation exist on the
tower itself with lines running down. That is why they should be
grounded to the tower at several points. Especially on a tall tower.

The tower has inductance just like any piece of wire has. Although the
tower inductance is less than just a length of wire it still has
inductance. When lightning strikes the top, the tower and lines all
share the current to ground. The farther up from ground you are the
higher the voltage will be with respect to ground. It can be
significant. Especially on a smaller tower. Leaving the tower only a
few feet above ground with your coax line is putting that line at some
point above ground that can have high voltage.

The best way is to run the lines all the way to the bottom of the
tower, ground them there, and then run underground to the house to
your ground rods. Don't forget to also run a ground lead from your
house ground to your tower ground system too. Bury it along with the
cables. That will give you more contact with the earth as well as
tying the grounds together.

Decoupling reduces the noise (rf current) traveling on the shield of the coax, both to, and from your shack, which would otherwise get pretty much direct coupled to your antenna.

Source record: 86410

I just made a 2m jpole antenna out of 1/2" copper pipes, like this one:

http://www.qsl.net/wrav/2mjpole.htm

On this web site the center conductor of the coax is connected to the longest pipe and the shield to the shortest.

Now looking at other sites I find the center conductor connected the the shortest pipe.

So what is the correct way to connect the coax?

Kjell Romma, Norway

The best would be to install a lambda/2 balun, so there will be no problem anymore. I did it many years ago. Great results.

Described in ARRL antenna book 17th edition page 26-10. probably also in more recent releases.

Hello,
you should try the Magnetic Line Balun (MLB).
It is a ferrite (not powderiron) core with a 9to1 ratio.
Take three wires, twist them and turn them around a ferritering.
Set them in series.
The lower winding to the (t)rx het high to the wire.
It simply works fine on the receiver and with a trx with a tuner.

I know this is not exactly the group to post in, but I thought
radio amateurs would have the best ideas for making one's own
antenna. I apologize if this question bothers anybody.

I just spent $800 at an EMC test lab to screen my device for
part 15 compliance. The used a Biconical antenna and a spectrum
analyzer to measure emissions from my device. I was wondering
how inexpensively I could I make my own system for screening?

How hard would it be to make half way decent antenna or antennas that
could listen to a broad spectrum?

Any websites out there have tips on making antennas?

Thanks a lot for your help.

My year 2000 ARRL handbook has instructions for a copper pipe 2-meter
j-pole, and the author says it doesn't matter which pipe you connect
the center conductor to. (He does mention a coax choke: 3 turns of
coax in an 8-inch coil, held together with tape.)

Theoretically, it doesn't matter. The bottom 1/4WL of a J-Pole is
simply 1/4 wavelength of a balanced feedline similar to the original
Zepp antenna. I would install a choke on the feedline, however, to
try to keep the feedline from being part of the antenna.

As a point of interest, what is the feedpoint impedance of a 2m
J-Pole if the short is removed at the bottom and the antenna is
fed at that point, aka the original Zepp antenna? Is that like
the Arrow Antenna's J-Pole design?

Hi Kjell

Electrically it doesn't matter, because a J-Pole consists of a 1/2 wave antenna sitting on top of a 1/4 wave matching section. Mechanically, one leg of the matching section is integral with the antenna to save the cost of a fitting.

However, in real life, connecting the center conductor to the stub lowers the receive noise level of the antenna slightly without affecting performance.
Albeit, placing three 1/16th wave wires extending from the top cap, sorta like a capacity hat, will do the same thing.

From: Jim Keller <jkeller@cox.net>
Message-ID: <kkf1q09beo04j38in4aqu2f4cev5gd42kv@4ax.com>
Source record: 86322

I have an HF9V vertical that uses about 36 radials. The radials are terminated at a square aluminum plate at the base of the antenna. I have about a dozen holes in the plate. The screws, washers and nuts to secure the ground wires to the plate are stainless steel. The lugs at the end of the ground wire are the type intended for house wiring. Maybe zinc coated over copper?

I would like to disassemble everything, clean it all up, then reassemble but this time using some type of protective coating on each connection to prevent moisture from getting in and disturbing conductivity to all connections to the plate.

Question is, what have others done to prevent antenna connections, such as ground radials from corrosion at their points of contact?

I've heard about Penetrox and was curious if it would work in this application.

I live about 5 miles from the Ocean and the vertical is located on a slope that gets watered at least once a week.

Thanks,

Jim Keller

>I am constantly receiving 3 S-Units better when using the Cobra.
I have to wonder about the source.

$90 for zipcord?

Well, opinion aside, I modeled this (each arm is a single wire, folded back on itself twice) and when I tried to run a SWR sweep in EZNEC from 2MHz to 30MHz in 0.1MHz steps, EZNEC stalled and gave up.

I suppose this may have been due to warnings of wires being too close. As it was, I pulled the zip wires apart 1.2" (0.1'). EZNEC wanted a minimum 6". I tried again with 1MHz steps, and the full sweep drew a line across the top of the chart (max SWR). Hoping for more resolution, I tried with 0.2MHz steps, and EZNEC stalled again. Third time is charm (so the saying goes), and with 0.25MHz steps - it stalled again.

Just measured the Arrow Antenna J-Pole and can report that it
*is* a Zepp design scaled for 2 meters. Here's the schematic:

```
Center
Conductor---------+
1/4WL + 1/2WL
Braid---------+--------------------
```

The center conductor and braid are usually reversed for a Zepp
but that really doesn't make a whole lot of difference. The Arrow
Antenna J-pole just uses an open stub instead of a shorted stub
like the average J-pole. The 1/4WL open stub transforms the very
high feedpoint impedance of the 1/2WL section down to a low
feedpoint impedance. The 1/4WL shorted stub of the average J-Pole
transforms the impedance from zero ohms at the short to thousands
of ohms at the base of the 1/2WL section. Somewhere in between
those two values lies the desired value of 50 ohms so the shorted
stub has to be tapped.

Actually, I think I like the Arrow Antenna version better for
homebrewing. The 3/4WL section is bolted to the base plate which
is easy. Then an SO-239 can be mounted on the base plate for attaching
the coax and a 1/4WL #14 solid wire can attached to the center of the
socket and be supported at the top by an insulator attached to the
3/4WL section. The Arrow Antenna version can be mostly aluminum while
the ordinary J-Pole, being 100% copper tubing, is relatively hard to
solder.

Hi Mike

I would suggest that the problem isnt so much in finding a good antenna
but calibrating the entire system so that you can measure the absolute
signal strength.

That may also involve a screened room and something to dampen the
reflections inside it. Depends on the required accuracy.

But to answer your question, any broadband design would work. It would
be smart though to use something as low gain as possible to avoid
pointing errors. For your purposes it might be possible to use the one
piece of equipment you had measured, take its actual radiated signal and
use that as a relative measure against new equipment.

Lots of websites! My favourite is http://www.cebik.com/radio.html

Cheers Bob VK2YQA

Hi Fred,

This is, really, a very common topic here. The praises heaped upon expensive "BalUns" comes at the cost for simple ferrite plus rather stiff prices added for advertising and the illusion of worth.

Simply take common garden variety ferrite cores and stack them up on a 12" length of RG-58. Very simple: one gozinta and one comesoutta. This alone will quiet noisy receivers, remove RF potentials on the case, cure rigs of instability; and make sprinklers and touch lamps settle down.

Consult the archives for 1:1 BalUns, ferrite chokes, et. al. to research the nuances of which ferrite you should use (or simply build the conventional coiled coax choke).

Hi Mike,

That would be the cheapest part of your quest and it wouldn't come
close to a start. The investment is in the shielded room and its
equipment.

==========

- - - - and if your antenna or feedline is balanced, just get a ferrite ring, about 2" in diameter, and wind on it a dozen or so turns of 18 or 20 gauge, twin, stranded, flexible, Radio-Shack speaker cable.

Transmission loss is sensibly zero. Just keep length of cable on the ring less than 1/10 th of free-space wavelength at the highest frequency of interest to avoid sprurious responses.

It's about time great, heavy, hanks of coax were removed from the handbooks. Ferrites have been around for at least 50 years. But I suppose authors must have SOMETHING to write about. ;o)

I agree with your comments about the testimonials. A piece of wire is a piece of wire.

Concerning NEC modeling; the segment lengths should be equal to the wire spacing. The wire diameter is also a factor to be considered. Anyway, to establish the validity of the segmentation, I model a parallel wire transmission line, and see if it is close to the expected impedance. The antenna appeared to use something similar to 300 Ohm ribbon, so half inch spacing is probably closer to the correct dimensions.

With copper wires soldered to a copper pipe busbar, I used several coats
of clear polyurethane spray lacquer. Five years later, it looks like
new.

Anything that will keep the water out of the joint between the two
different metals will do fine. The advantage of clear lacquer is that
you can see what condition it's in without disturbing anything.

A balun isn't primarily for this job, but it works here.
A balanced antenna plus a balun would be best.

There are those who say they can't tell any improvement with this, but that says to me that they have other and larger problems.

Hi C, I wish there was easy consensus on the subject, with comprehendible (to me) science behind why Baluns help. But in the end there is a general consensus of the unwashed, we non-phd's of radio engineering who desire the electrical isolation, control of feedline radiation when swr is a bit high, and agreed upon improvement in signal to noise ratio, which some argue theoretically cannot be accurate. For our distant worked stations or mobiles, we seem to have reason enough. I stopped trying to explain to the very friendly but rigid thinking folks at Radio Works (where my Baluns come from) - that I enjoy the configuration of a random wire end-fed with one-half the balun shorted to ground. "That cannot work" they tell me, yet not only did a real Doctor of Electrical Engineering release this noise-limiting design in an old issue of "Proceedings", but I have worked aircraft 3,000 miles away with reports of "loud and clear" (exactly how they sounded to me). It's one of the best antennas that doesn't work I ever had!

At least there have been friendly and interesting comments offered by all on this topic, and something to learn as the gurus weigh in ;-)

Jack

I do this at home, but I don't try to make absolute measurements.
You can easily use a dipole, just as the lab will do when they want an accurate look at a specific spike. You'll need to do this outdoors, away from emitters. For me that's a practical impossibility, as I'd have to cart the equipment quite a ways to get to a quiet site.

What I did, is to build a shield enclosure from double-sided PCB material, soldered together with brass reinforcements on the corners, and finger stock to seal the lid. I use a small pickup loop to feed my spectrum analyzer, or IC-R8500 receiver.

Use a small microwave tray to set your pcb up off the copper! :)

By itself, this will give you unreproducible and very frustrating results.
The next thing you need is some sheets of 3M Mosfoam. The stuff they ship chips in.
Black, squishy, carbon loaded foam. This stuff absorbs RF quite nicely, and you get double effect because what dosen't absorb is reflected by the copper for another pass through the foam..
Line all the walls with this, and you'll be able to make repeatable relative measurements.

Now, just find your highest spike, and kill it, repeat till it gets difficult.

You can find some notes on this at www.dvanhorn.org

Cec, I was well aware of what Chipman was about to write years before he wrote his most excellent, most reliable book on the subject of transmission lines. There are are very few errors. All of those which I have found can be attributed to the printer. But you don't find these unless you actually use the book, fully understand the book, and do some practical sums.

There are far too many people who use books as bibles because they have found them verbally convincing but who have never actually used them by inserting practical engineering numbers. No-one unfamiliar with numbers can call himself an engineer. More likely he is a plagiarising Old Wife.

I do not worship Chipman. I think he is still plodding around in his 90's. I don't worship anybody.

Whilst on the subject of reliability, I have very recently had a serious accident.

My corkscrew broke.

It can only have been due to metal fatigue and all the use its had. Probably made in Taiwan or Korea.

For 5 days, for one reason or another, I have been confined to the house without the opportunity to replace corkscrews. Yet there have been 4 unopened bottles of perfectly good wine in the cooler, with clean glasses. Calamity! Absolute misery!

But my long mechanical engineering experience came to the rescue. I discovered a 1/4" Philips screwdriver and a hammer. With lots of hammering I eventually drove the cork (of a bottle of Premieres Cotes de Bordeaux, sweet-white), inside the bottle.

The cork floats on the top of the wine and there's few problems with pouring. The cork remains quite intact. No contaminating bits to spit out.

So everything is now back to normal. I shortly expect to obtain a new corkscrew - this time with a spare.

Hic!

Hi Frank,

Well, my wires were separated by nearly three times that, it was
suggested by a warning window that it should have been 6" and all this
is immaterial to the design being Zip cord.

OK, so we proceed with an antenna that is "like" the topic, but is
spread out to attend to the modeler. I took all wires and separated
them by those 6" and did a SWR sweep from 2 to 30MHz by 0.2MHz and
EZNEC plunged on through them all without clutching up.

Results are
12 +j550 Ohms at 2MHz -11dBi @ 10ï¿½
resonates below 80M -6dBi @ 10ï¿½
1975 -j160 Ohms at 60M -4dBi @ 10ï¿½
570 -j890 Ohms at 40M -0.7dBi @ 10ï¿½
104 -j680 Ohms at 30M 1.1dBi @ 10ï¿½
440 -j610 Ohms at 20M 5.5dBi @ 10ï¿½
210 +j1300 Ohms at 17M 7.7dBi @ 10ï¿½
420 -j520 Ohms at 15M 8.2dBi @ 10ï¿½
173 +j404 Ohms at 12M 10dBi @ 10ï¿½

Hi Richard:

I have modeled wires separated by 0.5" as transmission lines, and gotten good agreement with the predicted impedance. Only problem, with an antenna of this type, is you exceed the 2000 maximum number of allowable segments. I think I can go to 2" spacing, with 2" segmentation, and will give it a try. I suspect I will get results very similar to yours. I also suspect -- but have yet to verify -- that these antennas will behave pretty much the same as a conventional dipole of the same overall length. Note that a 140 ft dipole resonates at 3.34 MHz.

73,

Frank

OK, cancel useless wire from base of tower.

I got that from your prior post.

> It can be
> significant. Especially on a smaller tower.

It took a few seconds to get your point but yes, it's a matter of how
far up the tower the coax departs the tower as a percentage of the
tower height. Since I'm planning a short (35-40 foot tubular crankup)
tower I'll have both a "high inductance tower" and a high pulloff
level in terms of percentage. Not good no matter how one looks at it.

That's a given.

> Bury it along with the
> cables. That will give you more contact with the earth as well as
> tying the grounds together.

The wire will be there but I doubt that I'll be able to bury it.

The whole (small) property is part of a forest of huge old hardwoods
several of which are crowded close to the house particularly along the
wall thru which I need to feed the coax. You'd have to see it to
believe it and it's only six miles from City Hall Philadelphia.

Digging a trench is not possible thru the tangle of roots on any approach from the tower to the wall. I'm not looking forward to driving ground rods thru this maze of underground lumber but I'll do it even if it takes some serious power drilling to accomplish.

What I could do is run all the cables to the bottom of the tower with shield bonds at the top of the moving section, another one at the top of the fixed section, another bond halfway down fixed section and the last one at the bottom of the tower. Which will also be surrounded by trees. There's a hole below the canopy big enough to accomodate a Hexbeam or some similar very compact HF antenna if I spot the tower correctly. Some contractor is going to have a really bad time digging the hole for tower base. From the base of the tower I'll run the cables and the carrier wire horizontally on the surface for a few feet then back up to the eight foot level to a tree trunk. Six feet would also work and the rest of the run would be per previous.

The good news is that the soil is eternally damp highly conductive dark loam . .

# 2550. Re: Home brew antenna for FCC Part 15 screening?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-22 02:58:21 UTC
From: Rick Frazier <rickf@rickfrazier.com>
Message-ID: <41A155D9.24C0070F@rickfrazier.com>
Source record: 86346

Mike:

If you're looking for absolute information, like the report the EMC test lab produced, you could spend from $50,000 for the "basics" for an open site (outdoors, away from large signal sources, hopefully nearby or where you live), not counting such things as a turntable for the Device Under Test (DUT), on to a Million or more for a fully shielded, equipped "Screen Room". 'Been there, done that, (both kinds). Keeping everything calibrated so the results are accepted by FCC and others can be somewhat spendy and time consuming too.

(By the way, I'd have really loved a bill as low as $800 for scanning a device for Part 15 when I was doing it.. preliminary scans often cost well over that!).

On the other hand, if you want to "get an idea" of what your device is doing, or to debug it after you have a scan in hand, you can surely get by with nearly any broadband antenna for the frequency range of choice and a fairly sensitive spectrum analyzer. These aren't the hard parts. The hard part is the time you're going to invest to scan your local environment, so you can document the "local emitters" so you know whether the emission is from your device or is ambient noise in your environment. Of course, you may also need to do some of your scans "off hours" (like 3am) when the local emitter isn't broadcasting so you can make sure your device doesn't just happen to emit at the same frequency... (I spent countless hours doing this as well. If most people knew what it took to get a new device accepted and into manufacturing, perhaps they wouldn't balk at the price as much.)

If you have access to a remote, open site (the ideal is somewhere that is accessible without 4 wheel drive, in a small box canyon or valley, nearly or completely ringed by mountains, and as far away from civilization as possible, to limit the number of nearby emitters... Of course, in this day and age, these are pretty hard to find, and I've known people to take an old airplane hanger and screen it with appropriate sized copper mesh, bonded together to make a very large faraday cage... (One place actually used copper window screen, soldering the edges together. Must have cost them a fortune, but it was pretty quiet, considering it was smack dab in the middle of one of the most RF polluted places on earth, (Silicon Valley) ).

Half way decent antennas that have pretty wide range aren't that tough to find. Think log periodic and you have a good start... Of course, they won't be calibrated like the ones the EMC lab has, but you can get a really good idea of what's going on, and later, you can "borrow" the antennas and use them for Ham use (temporarily, of course). At one open

site, we used three different, log periodics of overlapping ranges, and all worked pretty well. Of course, to get into the HF region, we had to put the antenna quite high from the ground so we could go to vertical polarization, which also meant the DUT had to be on a platform at equal height. Think about making an extremely well sealed, wood tower about 20 feet tall, with a turntable for rotating the DUT, all without any metal fasteners! Even the turntable was made without metal (billiard balls make really good non-conductive bearings if you do it right) with the rotator motor down at ground level. All in all, it would have been a lot more fun if there hadn't been a schedule deadline looming... Oh yeah, you should also be able to change the height of the receiving/sampling antenna so you can look for emission off of the horizontal plane of the turntable...

As I remember it, Create had a log periodic that covered something like 50 Mhz to 1.3 Ghz, and EMC test systems had one that does something like 80 Mhz to 2 Ghz... A quick search on the web shows that KMA makes one that covers 26 Mhz to 1.3 Ghz, and another that covers 13 Mhz to 30 Mhz, so it can still be done.

Good Luck

# 2551. Re: random wire antenna

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-22 03:29:55 UTC
From: Reg Edwards <g4fgq.regp@ZZZbtinternet.com>
Message-ID: <cnrmfj$7oj$1@titan.btinternet.com>
Source record: 86347

Let me try to summarise.

A simple thing like a balun does only two simultaneous things.

It changes the impedance presented to the receiver (or transmitter).

And, because it disconnects the usually slightly radiating feedline from the antenna, it changes to some uncertain extent the antenna's directional properties both locally and at a distance.

On receive, the change in impedance matters very little. It doesn't matter very much whether the impedances involved are 600 or 300 or 50 ohms. They are quite arbitrarily decided by the mechanical construction of the transformer and are arithmetically derived by (often wildly incorrect) assumptions of values for line and receiver impedances.

The change in the antenna's directional properties sometimes, but not always matters. It depends on the local environment and can affect such things as signal to noise and signal to interference ratios. But you never know until you've tried it.

The very general moral is - if there's an improvement in performance in any respect due to fitting a balun then keep it. If there's no improvement then you could leave it where it is or try to sell it back to the manufacturer. It will seldom degrade performance.

On rare occasions, fitting a balun can make matters worse. But once again you'll never know until you've tried it. And the "made worse" circumstances are never reported in magazines. This causes bias in the statistics.

It can hardly be called "engineering". But there's nothing else one can do in the presence of inevitable large uncertainties in the local environment. It's this piquancy which adds to the pleasure of both amateur and professional radio.

Professionals who have to earn a living play safe by predicting radio paths to be typically within plus or minus 15 or 20 dB. Amateurs have the time to spare to quibble about minute fractions of S-units.

And balun and antenna salesmen have no alternative but to hover around and attempt to make a living out of the suckers. Everyone has a right to make a living.

Hi Brian,

It always seems to be a compromise when it comes to lightning
protection. It is very difficult to get everything just right.

I have a small crank up tower too. I use a heavy flexible wire that is
clamped to the top of the top section and the other end is clamped to
the top of the bottom section. When the tower is all the way up the
wire is fully extended. This provides some bonding of the tower
sections.
When the tower is cranked down this wire is of little use because it
has a large loop that hangs there. In the summer time when the tower
is cranked down I place a clamp at the bottom to clamp one leg of the
fixed section to a leg of the telescoping section. Not the best setup
but that is about all you can do with this type of tower.
You have it worse with a telescoping tube. No way to bond it when it
is down. All you can hope for is somewhat of a friction connection
when down.

By the way, I don't have near the ground rods installed that should be either. But my lines all run under ground about 150 feet.

# 2553. Answer to Dipole Double-Resonance Problem

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-22 03:56:40 UTC
From: radio913@aol.com
Message-ID: <1d15af91.0411211956.278d6321@posting.google.com>
Source record: 86349

Hi,

Ok, so the other thread died out, but
I thought i should give the other answer
anyhow.

One poster infered one portion of the
fix, which was the height of the dipole
was increased from 3.5 ft to 6.5 ft.

The other change we made was with
the spacing BETWEEN the 1/4 wave
elements; i had originally made the
elements too far apart.

Bringing them closer together and
raising the height improved the SWR
and made the antenna resonant at
only one frequency within 88-108 MHz
(not including harmonics).

Thanks for playing!

Slick

At the beer/wine busts at Texas A&M during the 50's, nobody
could ever remember to bring a corkscrew so that's the way
we did it. Sometimes we forgot a bottle opener and used the
bumper of my old '49 Chevvy to open the beer.

Hi Frank,

I also note that the "Cobra" doubles the number of resonances across the 2 to 30 MHz spectrum with the resonances coming in adjacent pairs. Our sometime correspondent, Dr. Slick, thinks he invented this characteristic with his mystery, garden variety dipole; but it is a simple matter of putting a bend in the wire.

This one manipulation was also the foundation of the "fractal" antenna, but "scientists" gushed on with baroque explanations and hyperbolic claims to disguise a rather mundane oddity.

This is correct, and why I mentioned even 6" was "too much".

> > It can be
> > significant. Especially on a smaller tower.
>
> It took a few seconds to get your point but yes, it's a matter of how
> far up the tower the coax departs the tower as a percentage of the
> tower height.

The last was not a correct assumption. The distance across a conductor (and in this case it is also the distance to ground) is what allows inductance to create deadly voltage potentials. Any conductor in series with a lightning strike will exhibit the same characteristics. 6" above ground near the base of a tower can translate to as much as 9800v above ground, with just modest assumptions of a very average return stroke current of 25Ka with a rise time of 40Ka/usec. It has no bearing whatsoever how tall or short the tower is. It's not long (or high above ground) before you could see over 100,000v potential develop where coax leaves any tower too soon.

> > Bury it along with the
> > cables. That will give you more contact with the earth as well as
> > tying the grounds together.
>
> The wire will be there but I doubt that I'll be able to bury it.

Burying a grounding electrode conductor is normally a code requirement. But that is not what you have in connecting the tower ground system to the station ground, AC mains ground, etc. Those are bonding conductors, and they are in many cases required to be insulated. Not in this case, but I want you to understand the difference between grounding, voltage division from many grounds, and a bonding conductor between your station and the tower. The latter is to maintain equipotential, and will not carry more than just equalizing currents. It will be well within the capability of a #6 insulated wire, should you choose to use that. Personally I would go a little larger but #6 is as largest that NEC or NFPA recommend for a bond in *most* cases. So burying the bonding conductor is not a requirement, although to protect it that is exactly what most facilities do. Neither will burying coax feedlines help in lightning protection, unless you are counting on them by

design to be grounding electrode conductors! Pretty foolish but heh, if someone tosses feedlines out a window, they may as well short them to a ground rod and "bring it on". In that case any more than about 5,000v will breakdown the dialectric both inside and outside the coax, and anything nearby may be the next target before it ever reaches the ground rod.

> The good news is that the soil is eternally damp highly conductive
> dark loam . .
>
> > Gary K4FMX

That is very good news, and it makes your job easier. But good soil or poor soil, understanding what bonding provides is equally if not more important than having a ground rod at all. To rest on the laurels of highly conductive soil and ignore bonding, would be inviting disaster. Yes commercial tower design does require many shield "bonds" along the height of towers, but as I said, I applied a reasonable approach which the average short tower or mast-only owner could and would be likely to comply with - bonding at the top, bottom and station entrance. I suspect few go even that far.

You may or may not be interested in all the surge protection diatribe in my website, but it's there because so many unfortunate souls were mislead in this area. I do think you might benefit from it's coverage of what bonding does to protect both you and your station, and it is a lot harder for most to get a hold of then simple mast or tower grounding. It doesn't have to be.

$800 is about 1/2 day of test time at a typical EMC lab. If you got a conducted emission test, a radiated emission pre-scan in a shielded enclosure, a diagnosis of the failure, amelioration of the problem, and a radiated emission test on an OATS, all for $800, I suggest you buy a lottery ticket tomorrow, cause you're on a roll!

## 2563. HE3RSI: An antenna simulation challenge

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-22 11:08:12 UTC
From: "C.Aymon" <www.cyamon.com>
Message-ID: <41a1c864$1_3@news.bluewin.ch>
Source record: 86360

During the month of november 2004, a group of swiss radio-amateurs have the unique opportunity to use the antenna system of Swiss Radio International in Sottens. The call used for this special event is HE3RSI. Pictures of the antennas are available here http://www.hb9mm.com/photos/Sottens2004

The antenna has been build in the in the beginning of the seventies. Today, using powerfull computers and software, it would be very interesing to modelize the antenna and check if the expected and measured gains and patterns can be retrieved. For all of us who are interested in antennas simulations, I post here the structure and the dimensions of the Sottens antenna.

The antenna system consists of two antennas of the same structure. One antenna (A) is for the band 9..15 Mhz and one (B) for 15..21 Mhz. Both antennas are ''suspended'' on both sides of a reflector, please see the pictures to have a better view of the situation.

Here is the antenna ''A'' structure (all dimensions in meters):

1) The antenna consists of 8 full-wave dipoles, each of length 19.7m

2) The 8 dipoles are organized in two identical groups of 4.

3) One group consists of 4 stacked dipoles, in a vertical plane. The lowest dipole is at 22m above ground, then the second is 9.2m above the first, the third is 11.40m above the second and the fourth is 9.2m above the third.

4) The two identical groups of 4 dipoles are put side by side in the same vertical plane. The horizontal distance between the centers of the dipoles of each group is 21.33m.

5) All dipole are center-fed in phase via (a system of) transmission lines of the same length.

6) Each dipole is actually made of 3 parallel wires of 4.1mm diameter and 0.66m apart. The three wires of a dipole are in an horizontal plane.

7) The dipole groups are ''suspended'' in front of a reflector at a distance of 7.4m of the reflector.

8) The reflector consists of (abt) 120 wires, of length (abt) 46m, stretched between two towers of (abt) 63m heigh.

9) The whole system is rotatable and weights about 135 tons.

It would be interesting to have the gain and the pattern of the antenna on all amateurs bands from 7Mhz to 28Mhz.

I am ready to (try to) answer to any question, or provide any missing information.

To your keyboards ;)

Best 73 de HB9DBC, Chris

Well, I finally got a SWR meter for UHF and put it on my 2 meter colinear base antenna. The antenna is a Hustler CG-144 with radial/mast mount kit. It's a 1/4 wave phased with a 5/8 wave. It's best VHF swr is 1.2:1 @ 144.900 mhz.

I had tested it on 440 with my HT and it seemed to work so I got a SWR meter and tested it. My friend Dave KC0EMK also came over with his UHF ant analyzer.

Both meters show a varying SWR around 1.8:1 with a dip to 1.1:1 @ 440.500 mhz. Coax is 37' of Flexi 4XL with properly fitted PL-259's on each end.

What gets me is if this antenna performs so well on UHF and the swr's are not too bad, then WHY doesn't Hustler advertise it as a dual band antenna?

w8zr is a member of premium-rx and IIRC the project was mentioned in a favorable light by Greg (The list owner) shortly before the article was published.

There is a discussion group on the w8zr site where quite a few people have left comments and questions resulting from building and using the multicoupler.

It probably has a high radiation angle on 440 which
is typical of 2m antennas used on 440. An antenna is
a dual-band *by design*, virtually never by accident.

---

The free-space radiation pattern of a 1/2-wave dipole operating at ~3X its design frequency has a tri-lobe shape. Maximum gain occurs in two planes that are not perpendicular to the axis of the dipole, with a reduced lobe in the perpendicular plane.

Radiation patterns from your Hustler also will be different for these conditions -- which could explain why it is not marketed as a dual-band antenna.

Did you measure the original distance tip-to-tip, or did you measure 2X the
length of one side independent of the spacing in the middle?

A little clarification here. When I said "smaller tower" I was not
necessarily referring to a shorter tower but one that has less surface
area. (smaller face)

The main consideration is the distance up from ground that the cables
leave the tower.

A lightning strike is a constant current source. If it is a 20ka
strike the voltage across whatever it hits is going to raise high
enough to conduct 20ka. If you have a low impedance conductor (tower)
the voltage developed across it will be less than it would be on a
high impedance tower (smaller face tower).

That is why large communication towers have less problems with lines
coming off at higher points on the tower. More of the strike current

makes it to ground via the tower with the larger surface it has.

Leaving the tower at some height above ground with the cables is still
a division of the voltage like a voltage divider. The higher up you
are the higher the voltage you will see with respect to ground. But
what determines what that actual voltage goes to is the amount of
strike current and the amount of inductance between the cable exit
point and ground. Of course the cables leaving the tower will also
carry part of the current too.

>

It doesn't matter what you want to call a ground conductor. The point
here is if it can carry any lightning current you are much better off
with it buried in the ground. A bare ground conductor making contact
with the soil acts like additional ground rods. Why would you not want
that?

Burying coax feed lines will help with lightning protection. It
greatly increases the inductance of the lines to lightning. It also
helps to dissipate the energy to ground by the coupling provided. (ie
you get less at the other end)

You can't help but view them as "grounding electrode conductors" as
you may want to call them. After all they are connected to the tower.
They are going to carry lightning current if you want them to or not.
Might as well let them dissipate part of the energy to earth.

A large part of the lightning is RF. You have to treat it as such.

A good lightning ground also makes a very good antenna ground system.
( buried radial system) Think in those terms.

Hi Ken,

By this claim, so well in comparison to what?

>and the swr's are not too bad, then WHY doesn't
>Hustler advertise it as a dual band antenna?

This goes back to my first question. Matching is not the end-all,
be-all characteristic.

The antenna is 7' tall with a phasing lump probably up 18" or 20"
which provides a complex relationship with the remaining 5' or more.
At UHF, this combination of lengths/loading presents one incredibly
tall antenna that is several wavelengths overall. This would suggest
that favored UHF radiation is principally straight up. Of course, it
still radiates out toward the horizon, but in comparison, by far less.

Now, as to this advertising spec. of being 7' tall. That doesn't make
much sense given the description of 5/8ths above a quarter wave.
Those two figures alone add up to less than 7'. The phasing section
must be awfully long.

So Gene, you should have asked the question: if one has a circuit with a thousand resistors all connected in series and no current paths in shunt, how does one arrive at a different current through R1000 than through R1?

Perhaps because SWR isn't everything!

I suspect that if you measure this antenna's pattern, or simulate in
in NEC or a similar software suite, you'll find that it has a lot of
high-angle radiation, and that its actual gain out towards the horizon
is not wonderful (may even be negative, measured in dBd).

It'd be embarrassing for Hustler to advertise it as a dual band
antenna, but have to quite gain figures on 440 which show that the
antenna performs worse than a simple quarter-wave-plus-radials ground
plane antenna.

> thousand resistors all connected in series and no current paths in
> shunt, how does one arrive at a different current through R1000 than
> through R1?

I've already explained that twice, Jim. Your circuit example above
bears no resemblance to the discussion of distributed networks
involving EM wave transmission lines with a fixed Z0. The Z0 of
a transmission line forces the ratio of voltage/current to be
equal to Z0. The voltage cannot change without a corresponding
change in the current. Even if there is no physical shunt path for
current, there is always a path for the H-field to supply energy
to the E-field and vice versa. If it will make you feel any better,
feel free to consider the Z0-fixing of the H-field and E-field ratio
to be a shunt path for the energy involved.

If your idealized circuit above is a transmission line with a constant
Z0, modeled as 1000 resistors in series, zero resistance in shunt,
and carrying EM waves, the source of the attenuation of the current
is clear. The voltage and current will be attenuated by exactly the
same percentage. That's why the attenuation factor is identical for
voltage and current in the exponential transmission line equations.

1. The series resistance causes a drop in voltage along with a
corresponding decrease in the amplitude of the E-field.

2. Since the ratio of the voltage to current is fixed by Z0, the
H-field decreases by exactly the same percentage as the E-field.

3. Since the H-field decreases by the same percentage as the E-field,
the current decreases by the same percentage as the voltage. That's
why the attenuation factor is identical for the voltage and current
for the exponential transmission line equations.

For the Nth time, the moral is: Don't be seduced by a circuit model
solution if it yields invalid results for a distributed network problem.

If your above idealized configuration is a circuit and not a distributed
network, then by all means, use circuit theory on it. But using a circuit
model solution for a distributed network problem is like using a DC ohm-meter
to measure the feedpoint impedance of an antenna. I trust you know enough
not to do that. :-)

From: Joel Kolstad <JKolstad71HatesSpam@Yahoo.Com>
Message-ID: <Y6-dnaCVKOfLzD_cRVn-jw@comcast.com>
Source record: 86290

I'm in Portland, Oregon, USA. Over the weekend I strung a G5RV horizonally about 15-20' off the ground -- it'll go higher once I have the hardware to do so, however. It's connected to an Icom IC-745. In general, it's working in that I can get pretty good reception on, e.g., 20m from the east coast. However, I don't seem to hear any of the beacon states on 14.1MHz. Should I be able to? It appears that the US beacon state (W6WX) is somewhere in California, which seems like it should be plenty close, at least with 100W (i.e., I should at least be able to here the callsigns and the first dash.)

I also have a shortwave receiver that came with a loop antenna. It's not quite as sensitive as the IC-745, and you need to put it into SSB mode and tune off-center to hear CW, but it wasn't picking up anything either.

What you hear depends on the shortwave skip conditions. Very often,
you will be able to hear the East Coast and not hear California.
The ARRL has a new Shortwave Propagation Handbook. Here's some
more information: http://dzabcik.home.texas.net/propagation.html

# 2597. Zo and Ro

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-22 22:08:29 UTC
From: Reg Edwards <g4fgq.regp@ZZZbtinternet.com>
Message-ID: <cnto0t$40h$1@sparta.btinternet.com>
Source record: 86294

Not having much else to do at present I thought I would make a comment on Zo and Ro of transmission lines. For entertainment and educational value, of course, if you like that sort of thing.

The condition for which Zo of a transmission line is always purely resistive (Zo = Ro) is extremely simple. It is -

G = C * R / L

where G is shunt conductance, C is shunt capacitance, R is series resistance, L is series inductance, all per unit length of line.

Which applies to any line length, at any frequency from DC to UHF.

It is a shortcoming of the Smith Chart, with Zo always equal to Ro, that it does not make you aware of this and can lead you up the garden path if you are not careful. As has recently occurred on this newsgroup.

Don't get me wrong. I'm not against Smith Charts. They are graphically educational within their limitations.

Hi Jim,

The major corrosion problems occur when you mate dissimilar metals.
Copper to aluminum is probably the worst in my experience. Here in the
states, we mixed copper and aluminum wiring in houses for a while in
the 60's and 70's, before AL wire was completely outlawed. There were
two fixes developed to control the corrosion. One was a special alloy
for all fittings, screws, clamps, etc. that might came in contact with
either or both metals. I still see electrical hardware marked CU/AL to
indicate it is made from that alloy. Then a paste was developed that
would prevent the oxidation from occuring. All points where both
metals came together were coated with it, before and after assembly.

There are other combinations, some of which have galvanic properties.
There are anti-seize and other pastes to deal with some of those.
Sometimes, all you need is a good silicon based lube, liberally
applied and wrapped with shrink wrap and electrical tape to keep the
rain out.

Hi Richard:

Here, below, are the data from a 140 ft "Cobra" type antenna compared with a 140 ft dipole. I modeled #24 AWG, spaced 1", with 1" segments. My previous comment about 2000 segments maximum was incorrect, and NEC can go to 10,000 segments. As it is, the model contained over 5,000 segments, and took almost 2 hours to run. The NEC output file contained about 250,000 lines of data in a 14.5 MB text file. While the 1" segmentation is well below the minimum lambda/1000 recommended by the NEC manual, a transmission line with similar dimensions gave results very close to the expected value of 550 Ohms. These results could therefore be considered as a reasonable validation of the antenna model. Not sure why EZNEC cannot deal with such a model.

From an operational point of view there seems to be very little difference between a 140 ft "Cobra" antenna, and a 140 ft dipole. On some frequencies it is noted that the Cobra exhibits a lower efficiency.

The data are noticeably different from your results (note that at 2 MHz both our results show an imaginary part of >0), but probably due to the large difference in dimensions. I was not able to verify the number of resonances due to the very long run times. If I had attempted 0.2 MHz steps the program would have run for 8 to 10 hours and generated over a million lines of output data. I think what I need is 64 bit dual processor system to

tackle such a problem.

Most of the claims I have read on e-ham.net can be considered as unverifiable nonsense. I certainly agree with your comments on the design. As for "fractal" antennas, I do not really know anything about them, so cannot comment.

One thing that does come out of this modeling is that an antenna does not have to be very much longer than a 1/4 wave long to provide reasonable input impedances.

Incidentally my model was run in free space, so have no data on take-off angle. I doubt it would be very different.

73,

Frank

Wonder why Ramo and Whinnery say that's an approximation for low-loss
lines? If the R+jwL angle is equal to the G+jwC angle, doesn't that
make Z0 purely resistive?

> Tam/WB2TT

I'm not sure what you mean here.

I made sure that the end-to-end length of
each 1/4 wavelength section was the same
size for each section of the dipole. We
use aluminum tubing and hoseclamps for
adjusting the length.

But when i adjusted the space between
the two sections, the length of each
section was NOT changed.

And yet the SWR improved, and
there was a single resonance between
88-108 Megs, as it should normally be.

Hi Gary, the coax feedlines are definitely NOT grounding electrode conductors. Not only are they incapable of such by design and accordingly not authorized as grounding conductors, but they could never remain connected to sensitive equipment if it were so. Neither is the shielding on coax sufficient to provide equipotential bonding so they are not allowable bonding conductors either. If anyone wants to sacrifice their coax by not properly shield-grounding and installing the appropriate number of coax lightning arrestors (this means on the tower also) then they will turn them into very ineffective grounding conductors. Burying might help then, but only because you could guarantee a breakdown in the dialectric and where safer to have that happen than underground. I understand many operators allow this and simply toss them out the window, or ground them before a storm, but there is no good reason for it. Proper installation can allow them to remain connected to the equipment without sacrificing the coax or the equipment. Burying coax does not prevent induction by either capacitive or magnetic induction onto the shields of the coax from a nearby strike. If coax were enclosed in metal conduit that was grounded at each end, there would be protection from this. But proper installation of shield grounding and surge suppression at both ends maintains safe levels of energy on the

feedline and allows its connection to sensitive equipment.Of course in rare cases there is sufficient energy (such as a 200Ka+ return stroke current) to overcome any level of protection. But protected stations will certainly fare a lot better in those rare events than the unprotected ones.

Hi Bob, a caution to anyone using silicone for any part of a grounding or bonding connection: silicone is a dialectric, and is not appropriate for anything other than an outer component of waterproofing - which I gather you meant but might have confused some folks. The copper pastes (or alloy mixtures) which you mentioned are the appropriate internal and external coatings for electrical connections in lightning protection systems - which any ground radial system is also providing. These are available at most electrical supply companies.

Hi Frank,

Well, your segmentation at one inch intervals over 420 feet of wire
seems rather over-the-top, but I suppose you arrived at that through
your transmission line modeling. Perhaps I should attempt that myself
in my own TL models.

EZNEC, itself, offers segmentation and geometry tests and where there
are issues it will remedy them itself. For this turn in the road I am
simply the loose nut behind the steering wheel. The first pass I
offered here (that brought EZNEC to its knees) consisted of only 263
segments. I then spread the wires out to accommodate those issues
EZNEC reported but would not correct of its own volition.

Were your wires as close as conventional 3-wire zip cord?

>From an operational point of view there seems to be very little difference

It appears that your reader, Outlook Express (a piece of software crap
by the way) is line length limited. Comparisons were difficult at
best so I confined them to those above. I was going to do a
side-by-side comparison with the same 140' dipole, but it was
unremarkable when earth dominates the drive point Z.

Another explanation for variations may be simply found in the high
degree of Z variation across frequency, we do agree on the imaginary
sign and the values do track in the higher bands.

Dear Reg,

You say that it is a shortcoming of the Smith Chart that Zo equals Ro.
However, I think that is either a misunderstanding or just misleading.
The Smith Chart only constrains the normalizing quantity to be purely
resistive - not the characteristic impedance of a particular
transmission line being shown on that chart. My program, SmartSmith,
for example, allows the user to specify both an Ro and an Xo term for
all transmission line sections.

When it's all said and done, the Smith Chart only implements the
transmission line equation (as shown on pages 24-10 and 27-29 in the
17th Edition of The ARRL Antenna Book).

With my respects and best wishes,

What isolates the shield of the coax from carrying current?
As long as it is connected to the tower at one end it is going to have strike current on it whether you want it there or not. Nothing you can do about it. Paralleling other conductors will reduce it's total current but you still have to deal with it on the coax line.

If you don't want to call the coax shield a grounding conductor that's ok but that won't stop the current on it.

Who told you that you should put lightning protectors at the tower as well as at the building entrance? What good do you think they do at the tower other than cost more money?

If you use a radial system for a ground at the tower or several ground rods, the coax run under ground can do the same thing as a radial as far as dissipating part of the energy. Having a buried radial rather than one run in the air lets the ground soak up a lot more energy if it is buried. There will be much less energy at the far end of a buried radial than one run in the air. A radial run in the air will dissipate little energy to the ground.

With buried coax the ground acts like a large choke on the cable also. Exactly what you want. The ground increases the cables natural inductance.

This is the same reason that long radials are not as effective as more shorter ones in dissipating lightning energy. The inductance of the long wire gets too high and becomes less effective as a conductor.

If you don't think that buried cables helps reduce lightning energy at the other end try running a single insulated feed wire for your long wire antenna underground. See how much attenuation it provides to the signals.
Burying the coax does the same thing for part of the lightning energy.

Jim,

I have conceded. I simply do not know how to deal with someone who uses models to prove that models are misleading. Cecil's "reality", wherever that comes from, trumps all.

I have not measured transmission lines in the vacuum of free space, so I must rely on models. Since Cecil claims some sort of devine connection to model-less reality he clearly must be correct. (Probably explains his intimate knowledge of reality in the vacuum of free space.)

On the contrary - I don't believe in divinities at all.
That's exactly why I don't worship math models (like some
people I know) as if they possessed supernatural powers.

It is ridiculous to try to force a distributed network
problem to obey the rules of circuit analysis. The
distributed network analysis model was developed
specifically because distributed networks do NOT obey
the boundary conditions necessary for the circuit analysis
model to yield valid results.

When the only tool you have is a hammer, everything
looks like a nail. Math models are tools. Please
choose a valid one for whatever problem you are
trying to solve.

I guess one could infer that that if G / C <> R / L, and R + jwL <> G +
jwC, then perhaps there are losses. I would only add that there are
probably also small currents in shunt distributed along the line.

For those with a mathematical bent, alternatively stated, for the angle of
Zo to be zero, or for Zo to be purely resistive -

L * G = C * R

or

L / C = R / G

which relationship is derived from -

Zo = Squareroot( Z / Y )

Where line series impedance Z = R + j * Omega * L

and line shunt admittance Y = G + j * Omega * C

provided the angle of Z is equal to the angle of Y.

Which makes Zo = Ro + j * ZERO

Incorrect. First, a strike termination device is placed higher than other equipment with its own down conductor. Then a lightning arrestor and shield bonding are specified at the top of the tower, shield bonding along the path (up to three times) and at the bottom, then more shield grounding and another lightning arrestor at the facility entrance.

> If you don't want to call the coax shield a grounding conductor that's

Current is maintained at a safe level on the coax center conductor and shielding by the above.

> Who told you that you should put lightning protectors at the tower as

National telecommunication companies who specify them in white papers and engineering plans for lightning protection. I have been studying these systems for 18 months now and find this procedure consistently applied. The specific information is proprietary but all I had to do was ask for it. I found the information available via the USAF and other agencies I normally deal with was somewhat old, so I started asking commercial companies what they currently use, and could I have copies of their plans. That's where this information comes from. That and the National Electrical Code and National Fire Protection Association, October 2004 editions. Studying the NEC 250 grounding and bonding and the NFPA-780 offers more information to safely operate communication sequipment, especially during thunderstorms, than all the amatuer radio operators advice put together. Most of the amatuers giving this advice have no personal understanding of why or how this works, they just repeat stories or instructions they heard from someone else. Probably the biggest collection of dangerous information ever shared is what hams offer about lightning protection. Even the ARRL which makes an incredible effort to educate at the issue, has information so old in many cases it has not been used in best available practice for over ten years.

Your mistaken on this stuff Gary, we either shed or prevent lightning energy from coax by shield grounding, surge protection devices and sometimes encasement in grounded conduit. No plan or specification calls for earth-burying coax to deliver what you promise, and I believe your theory is electrically impossible, unless as I said over and over, the dialectric breakdown occurs, which means the installation was improper in the first place, or overcome by statistically rare events.

Cecil,

Do you s'pose that if the equality is perfect for zero-loss lines then
maybe it is an useful approximation for low-loss lines?

Do you really think R&W were proposing that this simple relationship is
more appropriate for low loss lines than for zero loss lines?

Jack,

I don't think you really understand all you are reading. It sounds like you are digging up stuff designed to sell a lot of protection devices.

As far as the NEC requiring grounding and bonding of structures, They want to be sure that there is a continuous bond on things they are concerned with. They don't always consider what they are grounding.

Do you really think that placing a down conductor of #6 wire on a tower with a 6 or 8 foot face (big tower) is going to make any difference in the impedance path that the lightning is going to see. Each leg may be 2 or 3" in diameter itself. The impedance of the tower will be so much lower than that wire. The lightning won't know the difference whether that wire is there or not.

Even if the added down conductor did carry a large part of the current it would get coupled to the tower anyway before it reached the bottom. That is what happens to the coax lines in reverse. Any energy that the tower is carrying is coupled to the coax lines whether they are grounded to the tower or not. You ground them at multiple points to prevent flashovers between the lines and the tower.

You can not keep the lightning energy off the coax lines or any other lines coming down the tower. They are all mutual. When those lines leave the tower at the bottom they are going to have some energy on them unless you have a perfect ground at the bottom of the tower.

A grounded antenna will keep voltage levels on the center conductor at a safe level. No need for a protection device at the top.

I agree that there is a lot of mis-information on lightning floating around. But don't cut all the hams short either. Some of them have

lots of experience in this area.
Think about what you read rather than taking in mounds of propaganda and repeating it.

Do you think that you can bury the feed wire for your long wire antenna and have it work very well? What do you think will happen to the RF on it? Will it make it all the way back to your receiver the same as it would if it were above ground?

Just a few thoughts on the subject.

Lightning conductors are most accurately modelled as DC to HF transmission lines - which indeed is what they are.

In addition to resistance they posses inductance, capacitance, a Zo and propagation constants depending on length and diameter. It takes time for a stroke to propagate down and along a set of conductors. It arrives at different times at different places in the system.

The generator is a high impedance, pulsed current source of so many thousands of amps. The voltage developed between a conductor, another conductor, and what's in its environment is Zo times the stroke current. Volts can leap across gaps.

Once in the ground current travels at a much slower velocity than along a wire. Voltages developed depend on arrival times at different places. A ground rod is a short length of line.

Frequencies of 100's of kilohertz are involved. Even reflected volts and currents occur. Ground conductivity can be allowed for.

Very crude approximations are involved. Nevertheless, any information about behaviour DURING a strike is better than none. It may be a matter of life and death.

It would be interesting to calculate, for a given strike current, the difference in voltage between the front and rear legs of a cow standing near to and facing a grounded antenna mast.

Radio hams, presumably endowed with more common sense, can always wear rubber boots while walking around their backyards carrying a field-strength meter in thunder storms.

> in my own TL models.

You are correct Richard -- It appears my segmentation is seriously "over the top". The segmentation was driven by not wanting a segment to be longer than the spacing. Some texts on NEC do recomend such constraints. So far I have gone to 16" segments, with 1" spacing. For the transmission line model it shows even better convergence. #24 AWG spaced by 1" has a characterestic impedance of 550 Ohm. My transmission line model is 100 ft long with 75 segments in each side. It would be interesting to know if EZNEC would produce the same result.

> Were your wires as close as conventional 3-wire zip cord?

No, as explained above they are #24 spaced by 1". Possibly I missed something there. Is the antenna made from simple 3-wire zip cord? Unfortunately NEC cannot model insulated wire, so not sure how that would effect the model. Is the VF very significant?

Very likely. How high did you place your model? Did you use the
Sommerfeld/Norton grouind model? Probably not really a factor at 30 ft, or
more, above ground.

Yes, by inference from close-up photography at the web site.

>Unfortunately NEC cannot model insulated wire, so not sure how that would
>effect the model. Is the VF very significant?

EZNEC can accommodate insulation, but I rarely fine tune to that
degree when I am looking at the panorama of SWR sweeps. Really, this
will only nudge things in the single digit percentage range and such
things are swamped from one Ham's situation to another's.

I placed it at the reported height, 35 feet, that raised the signal
levels 2 S-Units over a similarly mounted G5RV. ;-) I choose one of
two ground models when I work on these things: Perfect, or average,
high accuracy lossy. That height seems to be a commonly reported
value with those who put up wire antennas and have no tower to work
from, so it works for me as an "Everyman's" best.

Hi Frank,

I gave this several passes with various segmentations.

The best, flattest response appeared at 400 (total) segments over a
10M length of line of #24 separated by 1". This resulted in a
characteristic 575 Ohm line with a 1.045:1 SWR ripple over the 2 MHz
to 30 MHz band.

When I doubled and then tripled the segments, the low end got a little
whacked out (getting worse as the segments went up).

I was working from many segments down, so I did not lower the count to
your longer segments - maybe tomorrow, I was paying attention to your
(and EZNEC's) advice about segment length equaling line separation.

I never suggested such a silly thing! You mistake an earlier reference I made to a bonding conductor. Down conductors are sized according to code standards which provides a minimum for given elevation categories. 3/0 wire which is close to 1/2" in dia is the largest reqirement in NEC sizing table 250.66. In telecommunication applications, down conductors are normally sized to equal or exceed the size of the feed lines, and this means larger sizing yet. It's bonding conductors that burying usually serves no purpose except protection. One bond that is an exception is the station ground to utility entrance ground - that bond will carry ground potential rise current that hopefully bypasses the power connection at the back of station equipment. It must remain low impedance and high current capability, so additional ground rods are required along that bond if farther than 20'. Don't sell the NEC short. NFPA, which oversees the National Electrical Code, doesn't specify maximum protection, it specifies minimum protection standards. Industry does better where it sees cost benefit from doing so.

Actually this is bonding Gary, an important distinction to understand. A device is only grounded at a grounding electrode. All other connections are bonding for equipotential, to minimize voltage differences. The principles of bonding are not taught in the amateur radio or any other communications hobby. Only electrical enginners, electricians, and anyone who studies the electrical code and reference materials on bonding and grounding will understand this. It's hard to even communicate about lightning protection until the basics of protection by equipotential are understood, and this doesn't come from a casual read or anything learned in ham-world postings. At least not from what I've seen, which is about everything a search engine can find.

I didn't write the specifications that major companies are using, and neither did the companies selling lightning protection, although I agree there is influence there. Professional Engineers write these to protect equipment, personnel, and maintain operations, maybe not in that order. If they specify arrestors at tower tops, they must be trying to avoid damage that was not protected without them. It is no guarantee that damage is eliminated by their presence, I'm just relaying their usage - now.

>
> I agree that there is a lot of mis-information on lightning floating
> around. But don't cut all the hams short either. Some of them have

I don't cut all hams short. Richard Harrison (resident guru here on RRA) and others are thanked on my website for great information, their experiences, and helpful answers to questions. Many hams provided me with details about damage to equipment, and their humble honesty cannot be thanked enough. I have written many the best of the amateur websites discussing grounding and offered suggestions and references to improve their quality .

Here are a few excerpts you or others may have missed from the NEC:

Article 810.51 of the current NFPA 70, which states in part...

"810.58 Grounding Conductors - Amateur Transmitting and Receiving Stations.

Grounding conductors shall comply with 810.58(A) through (C).

(A) Other Sections. All grounding conductors for amateur transmitting and receiving stations shall comply with 810.21(A) through (J).

(B) Size of Protective Grounding Conductor. The protective grounding conductor for transmitting stations shall be as large as the lead-in but not smaller than 10 AWG copper, bronze, or copper-clad steel.

(C) Size of Operating Grounding Conductor. The operating grounding conductor for transmitting stations shall not be less than 14 AWG copper or its equivalent."

and Article 810.15, which states

"810.15 Grounding.

"Masts and metal structures supporting antennas shall be grounded in accordance with 810.21."

finally, 810.21, which states

"810.21 Grounding Conductors - Receiving Stations.

Grounding conductors shall comply with 810.21(A) through (J).

(A) Material. The grounding conductor shall be of copper, aluminum, copper-clad steel, bronze, or similar corrosion-resistant material. Aluminum or copper-clad aluminum grounding conductors shall not be used where in direct contact with masonry or the earth or where subject to corrosive conditions. Where used outside, aluminum or copper-clad aluminum shall not be installed within 450 mm (18 in.) of the earth.

(B) Insulation. Insulation on grounding conductors shall not be required.

(C) Supports. The grounding conductors shall be securely fastened in place and shall be permitted to be directly attached to the surface wired over without the use of insulating supports.

Exception: Where proper support cannot be provided, the size of the grounding conductors shall be increased proportionately.

(D) Mechanical Protection. The grounding conductor shall be protected where exposed to physical damage, or the size of the grounding conductors shall be increased proportionately to compensate for the lack of protection. Where the grounding conductor is run in a metal raceway, both ends of the raceway shall be bonded to the grounding conductor or to the same terminal or electrode to which the grounding conductor is connected.

(E) Run in Straight Line. The grounding conductor for an antenna mast or antenna discharge unit shall be run in as straight a line as practicable from the mast or discharge unit to the grounding electrode.

You've little description of the vessel you'll be in. If it has a
stayed mast of any height a common practice is to load the backstay thru
a tuner. If the stay is conductive to a metal mast and to a metal hull
at the lower end tune it from a gamma match. If the stay is insulated
tune it as a marconi. The taller the mast the lower the freq you can
easily match.

Well, that is pretty entertaining and
interesting, i will admit. However, the
result isn't very practical...

Most texts just assume lossless conditions,
so that R and G equal zero, so that Zo is
again, always purely real, and only dependant
on the distributed inductance and capacitance
of the transmission line.

You know, this seems to be quite a theory
problem regarding the Smith Chart. This goes back to
the heated argument on the Gamma reflection
coefficient using the conjugate of Zo in the
numerator.
Since i trust Les Besser more than
other people, i'm gonna assume that
you indeed CAN normalize a Smith chart
to a complex Zo. That is, a Zo that
is not a purely real impedance.

Here is a quote from your previous post where the discussion was about
the tower and lines carrying strike current.

>Jack Painter

>First, a strike termination device is placed higher than other
>equipment with its own down conductor.

Your reply when questioned about placing a down conductor in parallel
with the tower was:
>I never suggested such a silly thing! You mistake an earlier reference >I made to a
bonding conductor.

As far as down conductors go you need to read farther to see what they
are using them for. We are talking about towers here. No down
conductors needed. If you are talking about a building or wooden pole
mounted antenna then that's a different story.

The applications of grounding and bonding principles are not reserved
for an elite society of engineers and electricians as you might like
to think. They are free and available to all. There are no secrets
involved.
Quoting a load of authoritative directives is not a substitute for
understanding.

It is a play of semantics when you say " an important distinction to
understand the difference between bonding and grounding". I would
guess that it does not take too much study to understand that real
ground can not be half way up a tower. So whether you are "bonding" or
"grounding" a cable on a tower, the end result is unmistakably the
same.

It seems that some of the discontinuity may come from lack of basic
understanding of RF principles. Lightning is not just a direct current
event that requires only consideration for high currents.

As far as buried cables go:
I will ask the same question again that you avoided from last time but
instead provided mounds of quotes that do not address the point.

"Do you think that you can bury the feed wire for your long wire
antenna and have it work very well? What do you think will happen to
the RF on it? Will it make it all the way back to your receiver the
same as it would if it were above ground?"

This is a very relevant to "buried coax lines".

If R <> 0 and G <> 0, then there are losses. The only time a line is lossless is when R = G = 0 which, according to Reg, is only in my wet dreams about circles on Smith Charts. :-) For real world transmission lines at HF, (usually) R/Z0 >> G*Z0. When I was a member of the high speed cable group at Intel, I remember test leads designed for R/Z0=G*Z0 but they were expensive special order devices.

We apparently are more successful at designing very good dielectrics than in finding an economically feasible conductor with a couple of magnitudes less resistance than copper. Thus our ordinary transmission lines have a lot more series resistance than shunt conductance, especially open-wire transmission lines in free space. :-)

Nope, exactly the opposite. Apparently, they were proposing that this
simple relationship doesn't hold for highly lossy lines. Chipman also
has something to say about highly lossy lines.

# 2640. surveillance receiver aerial

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-23 20:13:12 UTC
From: zentace63@yahoo.co.uk
Message-ID: <a406d859.0411231213.76bee279@posting.google.com>
Source record: 86237

Hello

Hope someone out there can help!
I've just started a private investigator business.
Part of the equipment I use is a recorder/receiver unit (basically a sony tape machine with a receiver built on to it). The aerial appears to be a black plastic coated, bendy single wire 16cm long with a small 3mm (approx) screw thread on the end which screws into the receiver. It appears to be single core, in that, the screw thread is a solid piece (not like a two piece jack plug for example).

I want to be able to connect an external car ariel to the receiver as at present the receiver with the aerial screwed in is hidden inside the car and the reception is very poor.

Some questions:
Is the aerial single core? I naively thought all aerials had a core and screen.

Could I take a connection from the centre core of an existing wing mounted car aerial and run a single wire to the receiver inside the car?

If I used this method would the external car aerial have to be 16cm, same as the plastic aerial?

Can these small 3mm screw threads on the end of the existing aerial be bought from somewhere so I could connect my external aerial to the receiver?

I hope this all makes sense and I would be very grateful for any advice.

Thank you

made to a bonding conductor.

You're displaying dimensia Gary. You accused me of suggesting a #6 wire would be useful as a down conductor and I never said such a ridiculous thing. You misread the posts, or still don't understand most of the terminology that the entire electrical, fire protection, lightning protection and communication industry use to refer to bonding and grounding components.

in news:qBdod.15535$D26.3848@lakeread03... I said, and I quote:
"Burying a grounding electrode conductor is normally a code requirement. But that is not what you have in connecting the tower ground system to the station ground, AC mains ground, etc. Those are bonding conductors, and they are in many cases required to be insulated. Not in this case, but I want you to understand the difference between grounding, voltage division from many grounds, and a bonding conductor between your station and the tower. The latter is to maintain equipotential, and will not carry more than just equalizing currents. It will be well within the capability of a #6 insulated wire, should you choose to use that."

I'm not being condescending, if you're still confused there please say so, and I will try to explain it better.

> As far as down conductors go you need to read farther to see what they
> are using them for. We are talking about towers here. No down
> conductors needed. If you are talking about a building or wooden pole
> mounted antenna then that's a different story.

Its clear to me who needs to do the reading here. Your last shot was also wide of the mark regarding down conductors on towers. They are used on communication towers in exactly the same fashion as they are on any structure, to provide a dedicated path to a grounding electrode for the charge received by a strike termination device. A tower down conductor is

bonded to the tower frames in many places, that's the same as a down conductor on any structure is bonded to metal stairways, handrails, roof flashing, etc. on its way to ground.

> The applications of grounding and bonding principles are not reserved
> for an elite society of engineers and electricians as you might like
> to think. They are free and available to all. There are no secrets
> involved.

Please don't take my comments so far out of context. But you're right it is reserved, its reserved for those who pay the fees and time to subscribe to organizations that license the printing of the codes, and constantly discuss and explain changes, applications and plan future requirement for them.

> Quoting a load of authoritative directives is not a substitute for
> understanding.

> "grounding" a cable on a tower, the end result is unmistakably the
> same.

Neither should it be as oversimplified as your rebuttal. They are not the same thing and to misunderstand it would be to make deadly mistakes when applying those principles, both outside and inside structures where external equipments connect to people.

> It seems that some of the discontinuity may come from lack of basic
> understanding of RF principles. Lightning is not just a direct current
> event that requires only consideration for high currents.
>

This is a subterfuge to divert the attention from the basics we were discussing, and until that is resolved there is no room for discussion about protection design based on frequencies of structures and wiring in the near field, or the AC components of lightning.

> As far as buried cables go:
> I will ask the same question again that you avoided from last time but
> instead provided mounds of quotes that do not address the point.
>
> "Do you think that you can bury the feed wire for your long wire

> the RF on it? Will it make it all the way back to your receiver the
> same as it would if it were above ground?"
>
> This is a very relevant to "buried coax lines".

I ignored that question because I thought it had no relevance to anything here. Maybe you can rephrase what you are asking please? We are talking about shielded coax, and the relationship between lightning and the thin outer covering of coax, the coax shield, the inside dialectric, and the center conductor are quite unique and not convertible to a relationship with bare wire feed of some long wire. My coax feedlines are buried - so I don't hit them with the lawn mower! But it doesn't mean anything to lightning to have your coax buried, unless you hire a trencher to sink them deeper than the ground rods. In a near field strike there will be massive and sufficient energy to make all that shield grounding, bonding and placement of arrestors real important. And it won't matter where the coax is if all of those requirements are not met. if you think your coax is protected under your lawn, lay some turf over your radios and protect them the same way. It's a wives tale Gary, just like so many RF-wives tales, only there are more capable folks here to dispel those.

DOWN CONDUCTOR ON A BUILDING:
A down conductor on a building is a whole different deal than on a
tower. On a building the "metal stairways, handrails, roof flashing,
etc." are bonded to prevent flashovers as the down conductor runs by.
The down conductor is run because there is no better path to connect
to.

DOWN CONDUCTOR ON A TOWER:
My comments about a down conductor on a tower were based around the
fact that a down conductor on such a tower is useless. Tower joints
should be bonded to negate any resistance in the joints but a down
conductor the length of the tower is a waste of wire. I was trying to
point out that any down conductor, coax cables or anything else
running down the tower, including the tower, would all share the
lightning energy. It is impossible to isolate any part.

The fact that a typical tower has so much mass, and as a result much
lower inductance, in comparison to any down conductor that you could
hang on the tower negates it's usefulness.

And yes, I know that some people do install down conductors on towers.
Some people also hang pointy dissipation arrays on the top of their
tower too.

Some engineers and "communications managers" specify them also. Hams
don't have a lock on ignorance in this department.

I would guess then that the general library is also "reserved".

They are the same thing when we are talking about bonding or grounding
on the tower itself, which is where that discussion spawned from.
When you start jumping to other subjects then they may or may not be
the same thing.
Sometimes it is difficult to tell what you are discussing as you want
to throw so many things into the fire.

No diversion intended. Only a notice to read the other side of the
page.
I thought we were discussing lightning strike dissipation and
preventing it from reaching the shack. How can you ignore the AC
components? They are a major part of it.

>

BURIED COAX:
The relevance here was explained in my first post on the subject.
Let's try again. I asked if you thought that if you buried the feed
wire from your long wire antenna, it can be insulated if you choose
but a single wire, if you would get as much signal from your antenna
to your receiver as you would if that same feed wire was not buried
but run in the air away from ground. What do you think would happen to
the RF on that feed wire? Do you think that it would go unattenuated
the same as it would if the wire was in the air? Or would you loose
most of the signal if it were buried?

This is relevant to burying the coax lines coming off a tower and
leading into your shack. The coax shield will be carrying large
amounts of lightning energy during a strike that it receives when the
top of the tower is struck. Even though the coax is grounded at the
base of the tower. since there is no perfect ground system you are not
going to be able to dump all the energy to the tower ground.

For the moment forget about possible induced currents into the cable
itself from nearby strikes etc.

O.k. Gary. And I didn't mean to suggest a down conductor on a tower either, as its true there is little evidence that it carries more than 25-30% of the total energy with the tower carrying the balance. But it sure is specified in a LOT of places. I follow specifications to the letter unless there is clear evidence that in my particular facility it could be harmful or counterproductive.

The odd system or two specifies isolated tower down conductors. A majority proscribe down conductors and bonding the entire length, and another small percentage use an air terminal but bond it directly to to the tower legs and eliminate the down conductor. Please don't use PolyPhaser's toy lightning machine antics as evidence there. Big industry and government spend millions bringing rocket-triggered lightning down towers all the time, and if down conductors are still being specified they must help. How much, and if it applies to a typical ham tower, let the user decide I guess.

That's true, but maybe 25-30% of the energy directed on a faster path via down conductor means something, I have not seen why. The ESE Dissipaters however - another ball of ceiling wax and snake oil. Throughly disproven yet to this minute it ties up the Lightning Standards Group of the IEEE while they fight over the language to discredit it with. There is also at least one insurance company that discounts for use of the CTS (Charge Transfer System). There is no reliable science behind this theory but it hangs on...

A good library might have at least the NEC-70 (Electrical code). You can buy the NFPA-780 Standard for the Installation of Lightning Protection Systems for about $40 from NFPA directly. The October 2004 edition is the latest. The full NEC-70 is a lot more.

> Sometimes it is difficult to tell what you are discussing as you want

Roger that, sorry. My brain is awash with this stuff but it has been the most productive, interesting and generally most fun project I have taken on in years.

> I thought we were discussing lightning strike dissipation and

I think we were trying to answer a posters question about grounding the coax shield before it meets an arrestor, yes.

>
> For the moment forget about possible induced currents into the cable
> itself from nearby strikes etc.

Lets come back to that then, because it would require DEEP burying to avoid (It is commonly avoided by shield grounding, arrestors, grounded steel conduit, geometry, and distance). Anyway, yes, there would be some attenuation from a cheap wire insulator that was not designed to prevent RF from travel in either direction. But 95% or greater coax shielding with its dialectric inner liner is designed to keep RF from penetrating. While it allows travel on its inner and outer shield covers during some oddities of RF behavior, it does not allow attenuation of the RF signal by design. Then lets agree it's designed to be 50ohm, or 60ohm, if you want to use the anal British system (which we know is actually correct there Limeys). So if the point you were making was just that some inductance from earth is felt (even on coax) - I can't disagree, but neither would this wildly high impedance to even wet earth impress lightning in the least bit. In dry soil it would be invisible for all practical purposes. After all we stress the need to ground (via 8-10' of copper electrode) the coax shield (and the center conductor via arrestors) so what good is insulated earth? That was my point, and unless you count on unprotected coax breaking-down and arcing into the earth along its length, the burying part is just a no-gain event (just like a tower downcomductor???) Substantially all of the energy from a tower or antenna strike is already on the coax and it's first arrestor, top-shield bond, (middle shield bond if you like) and tower bottom shield ground (and another arrestor if you like) at the same time. Its even on the GROUND at the same time. They all rise in near unison within about 5 microseconds and fall in potential within 20-40 micro seconds. Where damage usually occurs is when unprotected coax has a distant ground only, and the voltage remains high its entire length as a result. This is where I believe you might tempt the voltage out anywhere along a buried path, maybe in thousands of little holes. It could just as easily happen laying on the ground though, so I fail to see what surrounding it in dirt can do. Apparently so do engineers who specify controls and installation procedures. That doesn't mean your argument can't be a good one. I just don't see it as that yet.

Hi Richard:

Found some three conductor zipcord and measured its dimensions: wire, stranded, #14 AWG, center to center spacing 3.5mm (0.138"). Experimented with a 100ft NEC transmission line model, with various segmentations from 4" to 16". Characteristic impedance agreed with :- 276*log(2*S/d) at 171 Ohms, where S is the center to center wire spacing, and d is the wire diameter. From your comments it seems EZNEC is in close agreement with my NEC program.

Applied the above dimension to a 140 ft "Cobra" type antenna at 35 ft above an average ground of: sigma 5 mS/m, and Er = 13. The antenna was segmented at 6". Hope the formatting of the following results is not totally destroyed by Microsoft's Outlook Express.

Cobra Antenna:

Freq Re Im S Eff.
(MHz) (450) (%)
2 29.8 93.8 15.7 66.3
3.8 109 637 12.6 83.4
5 251 58 1.8 95.4
7.2 999 -1381 6.8 99.0
10 516 1850 16.7 68
14.2 1287 -989 4.1 98.9
18 315 861 7.2 81.3
21.2 1096 -915 3.3 98.6

25 301 672 5.3 82.7
28.6 669 -712 3.6 98.2

140 ft Dipole compared

Freq Re Im S Eff.
(MHz) (450) (%)
2 8.8 -856 235 66.3
3.8 79 238 7.3 83.3
5 361 1127 9.8 95.4
7.2 1959 -2379 13 99
10 111 -195 4.9 68
14.2 2581 -2020 9.3 98.9
18 181 251 3.4 81.3
21.2 2225 -1871 8.5 98.6
25 188 233 3.1 82.7
28.6 1252 -1577 7.4 98.2

If the NEC models are correct there does not seem to be a lot of difference between the "Cobra" and a 140 ft dipole. Interesting to note that the Imaginary part of Zin, at 2 MHz is still >0. With 100 ft of 450 Ohm line on 2 MHz the loss is only 0.12 dB compared with 1.5 dB on the regular dipole.

Yes. I enjoy building. I usually build something, test it out, and go to the
next project.
>
> Q#2 - How does the "Assembly" of the Kit go ?

The kit is for an intermediate builder. It went well because the assembly is
well
documented. The is lots of mechanical assembly on the front and rear panels
because
of the number of switches, LED's and connectors.
>
> Q#3 - Does the "Finished" Kit perform well enough so that it is
> 'worth' the Money and Time to built it ?

It does a good job, and the construction is solid but the video amplifier
chip
is noisier than passive splitters. I have lots of receivers in the workshop
and
having the ability to drive 8 receivers is a godsend, however. I also
listen to low
frequency signals (below 500khz) and it does a good job in this region. For
lf reception I replaced the 0.1uf coupling capacitors with 1.0uf units.
>
> Q#4 - Are there 'cheaper' Lower Cost Ready-Made alternatives
> to this "Kit" ?

The purpose of the switches is to enable each receiver by controlling the
mute.
If you don't need to control the mute of you receivers and don't need a
preamp
you might look a some passive splitters from minicircuits labs. The passive
splitters
will have loss, however. A 4 way splitter has 6db loss; an 8 way splitter
9db, so you would
need a preamp.

Source record: 86252

One last note on down conductors. You can figure out what the inductance of a particular gauge of wire is. You can also figure out what the inductance of a particular size tower is. Just looking at the size difference you can see that the inductance of the small wire in comparison to the tower will be many times greater. That equates the many times greater voltage drop on the small wire. I would say that carrying 25% to 30% of the total current would be way optimistic. It is not just the gauge of the wire verses the gauge of the tower legs but how much inductance each presents. The cross section area of the face of the tower makes for less inductance as well as the size of the legs.

RADIALS
Buried radials make an excellent lightning ground system. An AM broadcast tower ground system is an example. Not only is it an excellent Radio ground but it is also an excellent lightning ground.

Running radials out from the base of a tower that you want to ground is a big plus in addition to ground rods I think you will have to agree.

It is suggested that many shorter radials be used rather than a few long ones in a lightning ground system. The reason is that the inductance gets too high to do much good as the length gets long.

Also long ground rods suffer the same fate. Too long and the inductance is so high. That is one reason why additional shorter rods are recommended rather than very long rods.

COAX LINES
Only talking about the energy on the OUTER SHIELD of coax here now. With buried coax lines coming from the tower they serve the same as a radial tied to the tower. They will dissipate some of the energy just the same as a radial will. And they do not have to be bare copper shield lines to do so either.

This was where I was going with the buried insulated single wire long wire lead.

By the time the energy on the shield of the cable reaches the shack, part of it has dissipated by the coupling to earth. Also the impedance seen at that end is much higher than it is at the tower end of the coax.
Just like the radial. The ground is a choke if you will.
Add ferite beads on a transmission line and you greatly limit the amount of RF current that gets past on the shield. That is what the

earth does to the coax line buried.

Hi Frank,

So it would seem.

Hi Bert,

You asked for comments, but you've been quite silent yourself. Would
you think that the extra wire was worth the $90? Would you think you
could trust testimonials, especially those claiming 2 S-Units gain
over a G5RV?

Gidday

I would suspect that the recorder unit you have is not really intended
to take a remote antenna.

Generally speaking an aerial will be a single core. The core and screen
thing you are thinking of is likely to be coaxial cable, what you could
join a aerial to a receiver with. It isnt normally suppose to pickup or
radiate signal.

Connecting the existing wing mounted aerial *might* work but you may
receive a lot of noise from car accessories/ignition etc. If your
receiver had a coaxial connector on it things would be a lot easier!

The length of the aerial is nominally a function of the operating
frequency but I doubt the unit you have would be critical in that
regard. It wont hurt to extend the aerial anyway you like. Try it!
"Real" aerials connected to transmitters tend to require tuning to work
efficiently, but since you dont know the parameters of the device you
are connecting to it there isnt much point trying to work it out..

Your biggest enemy of receiving a good signal will be if the aerial is
inside the car metalwork.. If you cant stick it out the window then at
least have it at glass level. You may find that mounting it on the sun
visor would be a good position.

Also note that mounting the transmitter and its aerial is also
important. Try and not bury it in a metalwork and if possible put it
next to a window.

Apologies for not being much help.

Cheers Bob VK2YQA (Sydney Australia)

Methinks you jumped to conclusions. Slick didn't ask when was
the last time I used a distortionless line. He asked when was
the last time I used the equation "G=C*R/L" for anything. I'm
using it right now. I used it yesterday to refresh my memory
about distortionless lines which I did use quite often before
I retired from Intel in 1998. If I presently held a job in the
cable modem group, I suppose I would still be using them.

I'm surprised the golden ears croud hasn't discovered distortionless
lines as a means of separating the gullible from their gold.

50' is the number generally used as the longest effective run of an
individual radial arm for lightning protection.

>
> Also long ground rods suffer the same fate. Too long and the
> inductance is so high. That is one reason why additional shorter rods
> are recommended rather than very long rods.

Up to 100' lengths of 1" copper clad steel ground rod are often sunk in order to obtain < 25 ohm resistance. < 5 ohm would be better but some soil condtions (such as dry sand) may be 1000 ohms. Bentonite and other similar soil-conditioners cannot be used effectively in sand, that is unless they occupy a deep 3' diameter hole. Here's an interesting anamoly in the NEC, which requires grounding electrode resistance to be < 25 ohm at the service entrance ground. If that cannot be accomplished, then a second ground electrode must be used. But there is no requirement to test the results after the second grounding electrode is added! It could easily be 400 ohms after two rods sunk in terrible soil, and yet it meets the code. There are few such glaring examples of short sightedness in the NEC, but engineers and contractors both have to be aware of these problems to design and build safe lightning protection systems.

According to both NEC and NFPA, the first grounding electrode coming off a structure may be shorter if conditions require, but then must be followed with a second electrode no shorter than 8' long and sunk to a depth of 10'. This is brand new in the 2004 edition btw. The minimum 8' long rod sunk to depth of 10' remains the code *minimum* in all other standards and applications where grounding electrodes are required. Distance between electrodes should be not less than sum of both their lengths. O.K. there is another little anamoly, since this does not take into account having to reach down 100' to find low resistance ground! Of course UFER grounds are also well accepted and commonly specified. This relates to another FAVORITE wives tale of hams, that is that tower foundations will explode if the grounding system goes into its concrete. There is not one documented case of this happening, yet the fable continues. It's true masonry and lightning do not get along well at all, but bonded conductors inside concrete foundations make it an excellent grounding system. It has been used world wide for decades.

> Just like the radial. The ground is a choke if you will.
> Add ferite beads on a transmission line and you greatly limit the
> amount of RF current that gets past on the shield. That is what the
> earth does to the coax line buried.

I understand what you are saying, thanks. Lets leave the ferrites alone though, because they can't shunt energy into dirt that doesn't have them, and if this was effective for lightning protection we would all use ferrite-shielded coax, right?

Back to the coax shield now - are you aware what is the most voltage that standard coax can carry? It's about 5,500v. At close to 4,500v coax dielectric breaks down and inner and outer conductors become "one". Close to 5,500v, the outer insulator of coax fails (similar to house wiring at 6,000v). Above breakdown voltage there will be flashovers to any object of lower potential, including the air in some cases. At anything less than breakdown voltage, you could hold the coax in a gloved hand and not feel anything. And neither would the earth, if that's where it was laying.

Let's review: It does not matter one bit whether you bleed off some RF energy out of a coax underground, because up to 5,500v of DC energy is going to get through with absolutely no affect from being near the dirt. And at over 6,000v nothing is going anywhere through that coax any more, it has reached breakdown and arcs over, melting and expelling the remains of its conductive materials all over the place. I have several such samples in my collection btw.

Finally, this will conclude my points about not burying coax for lightning protection:
Unless coax feedlines are protected by shield grounding and lightning surge protection devices in the proper manner and locations, there is no hope for its survival in even a nearby strike, let alone a direct attachment. If they are properly protected, it does not improve this protection to bury them. Perhaps it would increase the longevity of some surge protection devices and arrestors by limiting some RF energy they would otherwise be presented with. You would have to ask them that question. I have never seen a manufacturer

of these devices require feedlines be buried, maybe they are missing this too. They do however require the devices we have talked about.

It's of course fine if you want to hide coax, possibly reducing some external RF affects *and* the manufacturer says it is designed for below frost-line burying. Mine are buried too.

73 AND HAPPY THANKSGIVING

Those kind of lengths are only "last resort" ground systems if there
is no other possible way to get any sort of ground. The inductance
will be so high on that length that it will do little for lightning.

Unfortunately it is not just an old wives tale. Over the years I have
seen several tower bases cracked or exploded chunks out of them from
lightning strikes.

To effectively use the tower concrete as a ground is a good thing to
do. However it must never be the only ground. Ground rods also need to
be installed and connected to the tower or you will have the effects
that I have witnessed. The ones that I saw did not have any auxiliary
ground connections.

Well now, what if the DC component of the strike is only 5495 volts?
Still useless to remove most of the RF component of the strike? The RF
part does contain significant energy you know. After all isn't the
whole idea here to keep as much energy out of the shack as possible?
The DC part of the strike is usually easier to suppress with a ground
connection. The AC part is dependent on the inductance of the
conductor to get it to ground. Why not use all available means at
hand.

Jack, without trying to sound sarcastic I would recommend that you do
some reading about transmission line theory . Also some basics on
inductance and capacitance and how energy is transferred in their
fields. Outside of what the lightning protection people publish. These
may help you in your quest to become a lightning guru. It is fine to
read all the specifications of the NEC and other agencies that write
specs. But you need to remember that they are using one glove size to
try and fit all. If you understand a little more about how things work
you can come up with your own fixes to fit the situation much better.
You obviously have an appetite for this stuff. Spend a little time on
the theory side.
You have to be able to adapt to and use the surroundings available to
best advantage. The perfect system can not always be built.

Well I think I have had my run on this thread.

Best Holidays

I don't think there is one in EU. I do believe with a little
patience, a person could build one for a fraction of the cost. There
are some great links, files, pics, and a bunch of great guys on
Yahoo's Hexbeam group. There is an Excel spreadsheet that gives you
the dimensions for each band. In addition, there is a great website
by an EI who built one. I think his call is EI7BA and the article is
Hexbeam in 3 hours.
I own a commercially made hexbeam because I got a good price on it. I
would definitely consider building one. Don't expect miracles with
it, just good solid performance in a small package.

Look at it closely. It is three wires (Radio Shack rotor wire) joined at opposite ends to make one long wire. The 70 foot model actually has a "run" of 210 feet - 105 feet on each side. Funny, Radio Shack rotor wire comes in 70 foot rolls.

Attach ladder line to a middle insulator. Add up the cost and you'll save a lot by doing it yourself. I have seen a Cobra and it looks very well made but I have never used one.

The principal is called linear loading, and it is a very effective way of getting maximum benefit out of short antennas. It is far more efficient than coils. ON4UN's book talks a lot about it but I couldn't find much discussion on the effect of having the wires so close together. He does advise, on page 8-13 of the Third Edition, "make sure the separation between the element and the folded linear-loading device is large enough, and that you use high-quality insulators to prevent arc-over and insulator damage." He doesn't define "enough" and the phrasing of the sentence makes it sound like the only concern with having them too close is arc-over. On the same page, he warns modeling is "very tricky." From the discussion that follows on this thread, I would say that is an understatement.

Hi Frank,

Well on to other speculations....

Sometime later this morning, I will release a study in transmission lines that your discussion aided me with. It won't be so much about the lines themselves, but about a compendium of topics revolving around the Zc of the source, and what is called Mismatch Uncertainty.

I've done the grunt work, it just needs some introduction. However, as is typical with this topic, the thread will no doubt run to half a dozen comments, if that much. :-)

# 2691. Additional Line Losses Due to SWR

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-25 20:20:32 UTC
From: w9dmk@crosslink.net
Message-ID: <41a63e4a.6187176@news.crosslink.net>
Source record: 86187

Various authors provide curves or formula for computing the "total loss" in transmission lines, as opposed to the "matched-line" loss. Specifically, The ARRL Antenna Book gives an equation in Chapter 24 that seems to give results consistent with other sources (See the details at the end of this posting). However, there seems to be a fundamental flaw in the way in which the equation is applied.

In essence, the equation provides a loss factor which is a function of the matched-loss attenuation and the absolute reflection coefficient. The matched-loss attenuation is the value normally expressed in dB per 100 ft. and shown in tables or shown in logarithmic plots as a function of frequency. The reflection coefficient is introduced into the expression in order to increase the total losses as the SWR on the line increases.

After calculating a total loss factor it is applied to lines of any length based on the reflection coefficient at the load. In my opinion, it makes no sense whatsoever to provide an expression that is to determine the losses per unit length on a line and have it based on the reflection coefficient at the end of the line. If there is a mismatched load, and if the line has losses, then it follows that the SWR will become lower and lower the further we are from the termination. That being the case, would it not make more sense to say that the "additional" losses would be much higher at the load end of the line, where the SWR is high, than at great distance from the load, where the SWR is significantly lower? In fact, if the line is long enough, we know that the SWR approaches 1:1, and in a line with an SWR of 1:1 there should be no additional losses above the matched-line losses.

Nonetheless, with that non-sensical approach, the numerical examples shown at the referenced page and also in a later article on the subject of Highly Reactive Loads makes it quite clear that the loss factor is applied uniformly to the entire length of line.

If we take the expression for the total loss and apply it to small increments of line wherein the SWR is relatively constant, then it not only makes more sense, but it also predicts noticeably less total loss in longer lines.

I have embarked on careful measurements of lines severely mismatched (quarter wave open circuit stubs), and I can find no correlation between my measurements and the values predicted by the "total loss" equation. My measurements always show very low losses in comparison to the model.

I would be interested in corresponding with anyone who has other models for line losses, or anyone who has made measurements on quarter-wave stubs.

##########Equation and data taken directly from The ARRL Antenna Book, 17th Ed., page 24-9 ##################
(Eq 10) Total Loss (dB) = 10 log [ {(Alpha * Alpha - (AbsRho * AbsRho)} / {Alpha * (1- (AbsRho * AbsRho)) } ]

where

Alpha = 10^(ML/10) = matched-line loss ratio

AbsRho = (SWR - 1) / (SWR + 1)

where
ML = the matched-line loss for particular length of line, in dB

SWR = SWR at load end of line

The text then goes on with a numeric example using a 150 ft. length of RG-213 coax that is terminated in a 4:1 mismatch (SWR = 4:1, AbsRho = 0.6) at 14.2 MHz. The calculations for total line loss, per the above equation, results in a total line loss of 2.107 dB.

# 2692. Mismatch Uncertainty and an EZNEC transmission line sudy

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-25 21:00:23 UTC
From: Richard Clark <kb7qhc@comcast.net>
Message-ID: <hjfcq0pu47kcso3o296c2v1uje1h0bogis@4ax.com>
Source record: 86189

Hi All,

This topic is for the rare spirit interested in the finer points in discussions revolving around Source Impedance, and by implication, Source Impedance and the Thevenin/Norton equivalency. Please note that some may through reflex attempt to equate this with issues of matching efficiency, or maximum power, or conjugation. I will leave such side topics to others, and simply point out that those branches fall sway to the illusion of their accurately determining power, where no such accuracy exists. That is, they have fallen prey to the problem of Mismatch Uncertainty without having resolved it first.

In the spirit of so many other examples offered, I have struck upon a means to illustrate the problem of "Mismatch Uncertainty" for those loath to confirm this at the bench (such as my work offered in the past along with numerous references and examples).

That means was arrived at through discussions with Frank, ve6cb. That is, his details of design for a well behaved twin lead transmission line. That transmission line will be used as an EZNEC model to demonstrate the Mismatch Uncertainty through deliberate mismatches applied. I will add an artifice of an SWR meter in the form of a very Hi-Z load that is placed along the line to "measure" power (much in the way a Ham would take the difference of forward and reverse power readings to arrive at a total power applied to the load).

The Mismatches I will apply will be first at one end, and then at both ends to the tune of at "least" 10:1. From the classical math we can expect a range of power readings that are NOT true representations of the power absorbed by the load:

Reference
"Microwave Mismatch Error Analysis," HP Appl. Note 56, page 8
to find a simple expression of the range of error:
1 / (1 ï¿½ Gamma1 ï¿½ Gamma2)ï¿½
1 / (1 ï¿½ 0.8182 ï¿½ 0.8182)ï¿½
which reduces further to
1 / (1 + 0.6694)ï¿½
0.3588
and
1 / (1 - 0.6694)ï¿½
9.151
resulting in
-74% to +915% error in power determination WITHIN the line.

I will add a proviso in that the Source represented by EZNEC, and presumably by extension NEC, has no characteristic Zc; or rather I am not aware of its value. Needless to say, the numbers that will be published following this post will reveal that the SWR is in fact much higher....

Or I made a mistake. ;-)

I will no doubt garner responses that leap to my admission so I crossed that chasm for you.

Data will follow as my response to this post.

73's
Richard Clark, KB7QHC

I'm not sure what Zc is, but NEC sources have a definite, well-defined internal impedance: Zero. EZNEC gives you the choice of voltage sources, which are the same as NEC sources, with an impedance of zero; and current sources, which have an impedance of about 10^15 ohms -- infinite, for practical purposes.

The only one that falls immediately to hand is probably a decent
representative example. It is a piece of RG-8/U, also known by its
maker, Columbia, as 9913.

It is 5.334 meters long and is approximately 1/4 wave at 10.6 MHz,
which is where I made the measurement. In its open circuit
configuration, it measures 0.57 + j 0.3 ohms.

I am still struggling with some issues of how to interpret those
results, but two things seem to be clear - 1) the reactive component
is because I was about a degree too long for the frequency of
measurement, or there is enough stray capacitance at the open circuit
to transform into a bit of inductive reactance, and 2) the very low
resistive component doesn't seem to fit any math models that I'm
working with.

What do you think?

# 2698. FS: sma-to-bnc custom fit rubber covered antenna adapter

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-26 00:22:40 UTC
From: gulyas@earthlink.net
Message-ID: <12235960.0411251622.2fb9c0f3@posting.google.com>
Source record: 86195
Cross-posted to: rec.radio.swap,rec.radio.scanner,rec.radio.amateur.equipment,rec.radio.amateur.antenna

Do you have a need for a high-quality SMA-to-BNC rubber covered
factory look antenna adapter that is custom made to fit and protect
your H.T. or scanner radio?

Adapter allows you to:
Quickly change antennas to base, mobile or different style use.
Use the more popular and wider selection available of BNC antennas.
Prevent chassis connector wear or from coming loose due to antenna
changes.

Adapter features:
Gold plated contacts with a teflon insulator.
A low profile design with a rubber covering for a factory antenna
look.
The rubber base seals to the top of the radio with no spacers needed
for moisture and dirt protection.
The base also provides an excellent support for any length of antenna
or application.
No need to remove adapter once installed to make a quick and safe
BNC style antenna change.

Sizes to fit radio models:
Yaesu: VX-5R, VX-7R, VX-2R, VX-1R, FT-50-R, FT-60-R, VX-10, VX-150,
VX-110, VXA-100, VXA-120, VX-800, VXA-700

the 1/4 wave open end coax looks like a short circuit at the feed point. so your reading makes perfect sense.

It's been covered here, but to summarize, it is a 2 element full sized
element wire beam.

W9DMK) wrote:

Bob,

You might want to look at this paper:

http://users.triconet.org/wesandlinda/AIEE_High_Swr.pdf

|Various authors provide curves or formula for computing the "total
|loss" in transmission lines, as opposed to the "matched-line" loss.
|Specifically, The ARRL Antenna Book gives an equation in Chapter 24
|that seems to give results consistent with other sources (See the
|details at the end of this posting). However, there seems to be a
|fundamental flaw in the way in which the equation is applied.
|
|In essence, the equation provides a loss factor which is a function of
|the matched-loss attenuation and the absolute reflection coefficient.
|The matched-loss attenuation is the value normally expressed in dB per
|100 ft. and shown in tables or shown in logarithmic plots as a
|function of frequency. The reflection coefficient is introduced into
|the expression in order to increase the total losses as the SWR on the
|line increases.
|
|After calculating a total loss factor it is applied to lines of any
|length based on the reflection coefficient at the load. In my opinion,
|it makes no sense whatsoever to provide an expression that is to
|determine the losses per unit length on a line and have it based on
|the reflection coefficient at the end of the line. If there is a
|mismatched load, and if the line has losses, then it follows that the
|SWR will become lower and lower the further we are from the
|termination. That being the case, would it not make more sense to say
|that the "additional" losses would be much higher at the load end of
|the line, where the SWR is high, than at great distance from the load,
|where the SWR is significantly lower? In fact, if the line is long
|enough, we know that the SWR approaches 1:1, and in a line with an SWR
|of 1:1 there should be no additional losses above the matched-line
|losses.
|
|Nonetheless, with that non-sensical approach, the numerical examples
|shown at the referenced page and also in a later article on the
|subject of Highly Reactive Loads makes it quite clear that the loss
|factor is applied uniformly to the entire length of line.
|
|If we take the expression for the total loss and apply it to small

|increments of line wherein the SWR is relatively constant, then it not
|only makes more sense, but it also predicts noticeably less total loss
|in longer lines.
|
|I have embarked on careful measurements of lines severely mismatched
|(quarter wave open circuit stubs), and I can find no correlation
|between my measurements and the values predicted by the "total loss"
|equation. My measurements always show very low losses in comparison to
|the model.
|
|I would be interested in corresponding with anyone who has other
|models for line losses, or anyone who has made measurements on
|quarter-wave stubs.
|
|##########Equation and data taken directly from The ARRL Antenna Book,
|17th Ed., page 24-9 ################
|(Eq 10) Total Loss (dB) = 10 log [ {(Alpha * Alpha - (AbsRho *
|AbsRho)} / {Alpha * (1- (AbsRho * AbsRho)) } ]
|
|where
|
| Alpha = 10^(ML/10) = matched-line loss ratio
|
| AbsRho = (SWR - 1) / (SWR + 1)
|
|where
| ML = the matched-line loss for particular length of line, in
|dB
|
| SWR = SWR at load end of line
|
|The text then goes on with a numeric example using a 150 ft. length of
|RG-213 coax that is terminated in a 4:1 mismatch (SWR = 4:1, AbsRho =
|0.6) at 14.2 MHz. The calculations for total line loss, per the above
|equation, results in a total line loss of 2.107 dB.
|
|

Dear Dave,

Yes, I believe it does - that is, it makes perfect sense to have a low resistance and to have a near zero reactive component. What does not make sense is that the high SWR is supposed to produce outrageous losses. I don't see values that I can interpret as high losses - quite the opposite. Maybe I just don't interpret it correctly, but I would expect it to be several ohms - not 0.57 ohms.

In fact, and this is where it gets ridiculous, the examples in the ARRL Antenna Book would lead me to believe that the above quarter wave line would exhibit 20 dB of total losses. In order to get those numbers the SWR at the load of say 8000 would have to decrease to 1.01:1 at the source end in order to account for 20 dB in losses. (See the example on page 24-9 of the 17th Edition.)

# 2705. RE: Constructing a Cobra UltraLite Replica - Some Questions

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-26 04:33:23 UTC
From: Dave <dave@somehere.net>
Message-ID: <pkbdq059vnhst90ep9v27oaec53t90j83p@4ax.com>
Source record: 86202

I have read with interest the comments regarding the Cobra Ultralite. It's rare to see such unanimous praise on eHam so there must be something to it that people like so I guess that I will try to make one.

On the Radio Shack site I have found Catalog #: 15-1150 (3 conductor Rotator Cable - 100 ft. - $14.49)

My question to you guys is:

What do you think the impact of substituting 300 ohm twin-lead (RS Catalog #: 15-1175 - 100ft. - $10.49) for the 450 ohm ladder line would be?

If it would work, this antenna could be built for 25 bucks. Cheap enough to try it out and also much lighter than if made with ladder line.

Also, why is it necessary to have so much ladder line (K1JEK says to use the full 100ft.)? Seems like there might be a way to tune this antenna without so much lead- in wire. At my home I could easily get away with a 50 foot lead in. I guess that I just don't like the aesthetics of having to loosely coil up 50 ft of unused ladder-line or twin-lead and have it hanging on the outside of the house.

Appreciate any comments, thanks

Dave

You might go to the mfj web site and download the user manual for the
mfj-989c antenna tuner. Pages 7 & 8 give you certain balanced feedline
lengths to avoid, as well as several optimum lengths, and that info
would be applicable no matter what tuner you use to tune your dipole.

>Appreciate any comments, thanks

Hi Dave,

Bob offers a good point, inferentially through and to MFJ. However, it seems a longshot that MFJ could anticipate every unique length that would be most suitably paired against the spectrum of all available antennas that are out there.

But then, on the other hand, as Frank and I have shown: using three wires tied together in series or just one wire hardly makes any difference. As far as that goes, you stand to achieve a better match by simply running all three wires in parallel as a "fat" conductor. Don't take this advice to the bank, tho', as much advantage as there is there will be as unnoticeable as any combination of those three wires woven into a cat's cradle.

If you want to believe in testimonials, you could as easily join the cfa cult.

If you want to try ____ (fill in the blank), this is certainly the group that has at least one, two, or more who've already been there - no shame in that either, no one comes here simply to find boring talk about dipoles. I've tried to make a lot of these suckers sing. ;-)

Hi Bob,

Thanx for the explicit results. Now what is needed is the explicit expectation. I note that you circumspectly describe it as being
>ARRL Antenna Book would lead me to believe that the above quarter wave
>line would exhibit 20 dB of total losses. In order to get those
>numbers the SWR at the load of say 8000 would have to decrease to
>1.01:1 at the source end in order to account for 20 dB in losses. (See
>the example on page 24-9 of the 17th Edition.)
which is an inference which being an interpretation is open to errors of mis-interpretation.

Reference Data for Radio Engineers, "Mismatch and Transducer Loss," "One End Mismatched," pg. 22-12:
Transducer Loss = A0 + 10 ï¿½ log (Pm/P) decibels
where
A0 = normal attenuation of the line
Pm = power that would be delivered were system matched
P = power delivered to the load

Of particular note is that this is one of my references as to the nature of Source Z which is often neglected in academic treatments with the presumption that the engineer has already been schooled in the nature of Real sources (this may shock some complaisant readers here). However, this citation offers that explicit lesson in figure 10 and makes use of this commonplace characteristic in illustrations of Mismatch Uncertainty. They go as far as to explicitly offer a section entitled "Generator and Load Mismatched." You may wish to review this treatment as it offers the math that would present the most loss available in a line, above and beyond the typical charts offered for line loss (which are confined to both ends being matched).

the cases they talk about in there are figuring the loss in power that you
would be supplying to a load. in your case the load is an infinite
resistance so it receives zero power which is what the arrl book says... in
this case all the power that is sent down the line is reflected back minus a
little bit of heating so the swr at the feedpoint should be near infinite,
but not quite. the actual loss in the wave going down and coming back is
very small hence the very low impedance. this is an effect that is used to
make coaxial stub filters and transformers.

Hi Dave:

There is not the remotest possibility that the radiation efficiency of a "Cobra" antenna is any different than a conventional dipole of the same length. The antenna, admittedly, does have different impedance characteristics. With the specified length of transmission line, it may be easier to match with a typical antenna tuner. In particular at the low frequency end, resulting in a slight, but insignificant reduction of transmission line losses. I would recommend experimenting with transmission line length to determine the best match. The losses on 300 Ohm ribbon will be higher than with 450 Ohm line.

If anybody is interested I have an Excel spread sheet comparing the input impedance of a 140 ft Cobra with a conventional 140 ft dipole. It is then a

simple matter to predict the transmission line losses.

The use of zip cord for an antenna introduces another variable which is not easy to predict. The dielectric properties of the insulation may be less than ideal, and could introduce additional losses.

I would treat testimonials by users of the antenna with extreme caution.

73,

Frank

'Scuse me for butting in here but the message is that a hexbeam will
not compete particularly well in the pileups against 2-3-4 element
full size yagis so don't expect any miracles with a hexbeam in this
respect. In general a full size 2 elemment yagi will outperform a
hexbeam by a few dB here and there. Which should be intuitively
obvious. Compacting any "beam" antenna results in performance
compromises vs. full size versions. On the forward gain side of the
hex it's only a tad better than either lobe from a simple dipole at
the same height. Which is to say that if you're S9+10 on the other
guy's S-meter with a simple dipole a hex can be expected to kick his
needle to maybe S9+13 or some such no-counter. The "miracles" in
hexbeams vs. simple dipoles lies in it's meager but often quite useful
F/B ratio, it's steerability with inexpensive rotators and a few other
attributes which make it a good choice given restricted installation

conditions which preclude the use of full size 2 element yagis. Google W4RNL and dig into his website for his analyses of hexbeams and their wire beam cousins.

# 2715. TX Distance question

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-26 15:14:46 UTC
From: James <Nonethanks@NOSPAM.com>
Message-ID: <KMHpd.58953$Ro.2196328@news20.bellglobal.com>
Source record: 86212
Cross-posted to: rec.radio.amateur.antenna,rec.radio.amateur.dx,rec.radio.amateur.misc

Hi Folks

I have limited experience (ok almost none really) with respect to Amateur Radio outside of the 2M band. However I just recently got my code ticket & installed a radio on my sailboat. I am using a TS-50 with an automatic tuner and a long copper wire to the top of the mast (probably 50 feet or so long).

My ground plane/counterpoise consists of tying the ground to a large aluminium area in the stern of the boat with a copper foil.

My very first contacts were established with 2 land stations on 14300 at 100W that were about 1000 miles away. They both reported that my signal was good and that it sounded like I was "sitting right next to them". I have no idea if this was a good distance, great, or mediocre.

I realize that propogation variables prevent anyone from giving a really clear answer to this question, but in general, what sort of distance should I expect to achieve? I'm trying to decide whether I need to improve my antenna ground by adding a dynaplate (costly and requies the boat to be taken from the water for installation) or whether the range I am getting is decent.

Can anyone comment?

Thanks

## 2716. Short anchor bolt problem

Newsgroup: rec.radio.amateur.antenna

I am about to put up a tx-455 self supporting tower. The site
currently has a concrete pad, which has been described to me as
follows: The pad is 5' X 5' and about 3 feet deep. The pad is
heavily rebarred, and pinned to 30 feet of bedrock with 3 foot
epoxeyed bolts (4 of them). The bolts are about 24 inches into the
bedrock. There are 3 anchor bolts sticking out of the pad which
perfectly match the base plate of the tower. Here's the problem. Those
bolts are 12 inches in length 9 inches in the concrete and
3 inches extending out for th tower base. If I guy the bottom
section and use a fairly light antenna (HF quad) will I be okay?

Dear Wes,

I have downloaded the pdf file and printed it out. It's tough reading. I hope that MacAlpine agrees with what Dave and Richard are telling me, because their responses seem to be correct and are exactly what I was afraid of - that I've been sucked into another example of the strange terminology used to describe "losses".

I have always thought of "loss" as a conversion to another form of energy (typically heat energy) which is lost from the system. Apparently, the kind of "loss" being described in the example that I gave is not a loss at all. It's more like "return loss", which is also not a true "loss" in my thinking. In other words, it seems that the "Additional Losses Due to SWR" are not losses at all, but are simply a measure of the power that "could" have been delivered to the load were it not for the mis-match.

Hi Bob, I'm still at my relatives' house posting through Google. I'll
expand on this when I get back to my computer.

Those equations in The ARRL Antenna Book (15th Edition) make an assumption
that may or may not be true - I don't know. What they are assuming is that
the losses are due to the additional power associated with high SWR. In
general, if the forward power is 100w for the matched case and the sum
of the forward and reflected power is 300w for the unmatched case, the
losses will be three times higher for the unmatched case. That seems a
reasonable assumption. However, rho at the shorted or open end of a stub
is equal to |1| so rho^2 will be equal to 1. That puts (1-rho^2) = 0 in
the denominator of the equation and makes the addditional losses undefined.

> In fact, and this is where it gets ridiculous, the examples in the
> ARRL Antenna Book would lead me to believe that the above quarter wave
> line would exhibit 20 dB of total losses. In order to get those
> numbers the SWR at the load of say 8000 would have to decrease to
> 1.01:1 at the source end in order to account for 20 dB in losses. (See
> the example on page 24-9 of the 17th Edition.)

Here's an example. Assume 100w is delivered to the load for both the
matched and unmatched conditions. Assume 3dB matched line loss in the
transmission line. Assume an SWR of 5.83:1 (rho=0.707) at the load for
the mismatched condition.

Forward 200w------------3dB loss-------------Matched Load 100w

Forward 400w------------3dB loss-------------Mismatched Load 100w
Reflected 50w both Forward 200w
directions Reflected 100w

The equations gives an additional loss of 5.44dB. This is based on an
assumption that the losses are directly proportional to forward power
plus reflected power.

Remember that at the mouth of the stub, the impedance is equal to
(Vf + Vr)/(If + Ir) so, knowing the Z0, that should allow you to
calculate those four values existing at the mouth of the stub. From
that, you can calculate the total losses. More when I get back.

# 2719. Re: Constructing a Cobra UltraLite Replica - Some Questions

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-26 16:53:48 UTC
From: Craig Buck <k4ia@cox.net>
Message-ID: <wcJpd.4391$SA.1644@lakeread02>
Source record: 86216

The whole point of the Cobra Ultralite is not some magic achieved by using a fat piece of zip wire for the antenna.

The point is using linear loading to make a very short antenna that will work on all bands. The antenna uses 3 wire rotor cable - easily found at any Radio Shack store. Each side is constructed so as to connect the three wires into one long continuous wire. 35 feet on each side becomes 3x35 or 105 feet of wire. You can see this if you look closely at the picture on the website. It is a whole lot easier to tune 210 feet of wire on 160 - 10 meters than it is to tune 70 feet of wire.

```
------------| |----------
|-----------| |---------|
|------------center----------|
```

Go ahead and substitute the 300 ohm - there is no magic to the feedline but as others have pointed out, the 300 ohm cable will have higher losses. Whether it is so much you would be able to tell any difference is conjecture.

There is no magic to the length of feedline either. Certain lengths will transform the antenna impedance to something unacceptable. If you have trouble tuning on a particular band try adding or subtracting some feedline and you will get away from the problem. Cebik as an article on his website about this http://www.cebik.com/gup/gup7.html

Propagation will have a HUGE effect on your distance capability. Under good conditions your station should be able to work any point on earth. On the other hand, when the 14MHz band "goes out" (which at this point in the sunspot cycle will happen pretty much every night) you'll be lucky to work 30 miles.

I think the ground you describe should be more than adequate. (many land-based mobiles settle for something MUCH, MUCH worse!)

You'll need lower frequencies for nighttime operation. 7MHz and 3.5MHz. The antenna *may* (or may not) be too short for effective operation on these bands. Try it, the worst that can happen is the automatic tuner will refuse to make a match. (I think you'll probably be OK on 7, 3.5 may be a problem)

Good luck!

|Dear Wes,
|
|I have downloaded the pdf file and printed it out. It's tough reading.

Yes. But the ITT Reference Data For Radio Engineers uses this paper
as a reference.

If you have Mathcad, a sheet that implements some of the equations was
included as a reference in my Balanced Transmission line paper.

http://users.triconet.org/wesandlinda/LineCalc.mcd

|I hope that MacAlpine agrees with what Dave and Richard are telling

|energy (typically heat energy) which is lost from the system.
|Apparently, the kind of "loss" being described in the example that I
|gave is not a loss at all.

Yes it is. A simple-minded way of looking at it is if the SWR is
greater than unity then increased current is flowing in the line. The
line has resistive loss, so the I^2*R loss increases. The current
isn't constant (there is a current standing ratio, ISWR, just like a
VSWR) so there are peaks and valleys in the current and as you have
figured out, the longer the line and the higher its nominal loss, the
lower the ISWR is at the line input.

So the loss per unit length is non-linear and varies with distance from the mismatch, but it is a real dissipative loss.

For those interested in the loss in the shorted or open stub case, maybe this will be of interest:

http://users.triconet.org/wesandlinda/Stub_Matching_Loss.pdf

## 2723. HF Antenna Pickup Truck

No, but does your truck have stake pockets? There's an outfit that makes antenna mounts that fit in the stake pockets of pickups. I got one for my Ranger to mount a 10M Hamstick. Works pretty well and is a rugged mount. It would probably handle something a lot bigger than the Hamstick. Can't remember the name but they advertise in QST. I had tried a magmount in the middle of the bed but couldn't tune the Hamstick there. I'd guess you'd have the same problem due to the cab. Using the stake pocket mount (in the rear-most pocket on the pasenger side) it works great.

OTOH, a friend of mine runs a screwdriver antenna mounted to the rear wall of his toolbox in his big Dodge PU and it seems to work OK...

>cab....tnx...Gary, K8BY

There are two aspects to this: mechanical and electrical.

Mechanically, I'd imagine you'll be OK. A Hamstick is pretty thin,
and wouldn't have a large amount of wind-drag force on it. Assuming
that the toolbox is solidly constructed, the magmount's grip on its
roof would be sufficient to keep the antenna in place, and the drag
and torque on the toolbox lid's hinges probably wouldn't be enough to
matter. If I were you I'd arrange to snub the feed cable - clamp it
down to the frame somehow, so that if the mag-mount does pop loose you
don't find yourself dragging the antenna on the road behind the vehicle.

Electrically, there are a couple of issues. For one thing, if the
tookbox is immediately behind the cab, this arrangement might put the
Hamstick quite close to metal portions of the cab roof or uprights.
This sort of close antenna-to-body coupling tends to reduce the
antenna efficiency. Keep the antenna as far away from the metal body
as you can safely manage.

From what I've read, HF magmounts often don't have enough coupling
capacitance to give a really satisfactory grounding, even when mounted
right on the roof. It's usually desirable (and often necessary) to
run a short, fat grounding lead from the antenna base/feedpoint to a
solid grounding location on the vehicle frame. You should probably do
something like this if you do decide to mag-mount on the toolbox.

# 2728. Kenwood KAT-1 auto ATU - help?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-26 20:17:54 UTC
From: harrogate2 <harrogate2@ntlworld.com>
Message-ID: <SbMpd.604$mD4.368@newsfe2-gui.ntli.net>
Source record: 86125

Lucky chap that I am I have been given a Kenwood KAT-1 auto ATU but without manuals.

I have spoken to Kenwood UK who advise that there are two control lines, TS and TT, both of which are listed as 'in/out.' I intend to use it with an Icom 706 which has ATU control lines marked TKEY and TSTR - I have a fair idea what these do and how they work.

Does any kind soul out there have a user or service manual for the KAT-1 and could tell me the functions and voltage levels of the TS and TT lines are please, or have such an ATU and could pass on any experiences?

Thanks in advance.

James, considering you most likely have an ungrounded counterpoise instead of a good ground commonly employed, I think that's outstanding distance from a sailboat. In many cases during daytime operation, I have heard the Mobile Maritime Nets have to shift around to various operators before they could have copy as good as you describe, and from a lot less distance. If all you intend to use the radio for is hobby work on the 40 meter band, why mess with success? However your 50' of wire should typically also tune up on 2182 khz sufficiently for the distance commonly covered by USCG Groups and Caribbean RCC's (about 200 miles). Canadian Coast Guard Radio stations will often answer vessels as far as 500 miles away. Higher bands of maritime mobile channels would be better of course. I'm sure you're aware those require a separate station license on your vessel. Good job on installing your station. If you come up on maritime mobile maybe we'll get to talk someday.

Bob, your program can probably calculate the input impedance, Rin + j*Xin,
of a line having Zo = Ro + j*Xo, with given attenuation Alpha dB, and given
phase-shift Beta radians, with a terminating impedance Rt + j*Xt.

Which is a commonly needed quantity on the way to calculating the ultimate,
all-important, single number, transmission efficiency.

But can you do it with nothing at hand except a Smith Chart?

Bill,

50 foot is only too long if you are sticking with the resonant length
situation. Which is not really necessary with his setup. In fact he
probably gets better versatility with the longer length. Just an opinion.

>a metal toolbox?

Hi Gary, If your toolbox is like mine, it is Aluminum, and the mag mount won't stick. I attached a small steel plate on the top of the box and use it for a 2M mag mount.
For my homebrew HF mobile antenna I use a mounting system on the backside of the box. I get good results with my bugcatcher type antenna on 80m-17m mounted in this location. The loading coil is about 1 foot above the cab top. Since a Hamstick is continously loaded, and may not be as efficient as a bugcatcher, you may not have similar results, mounting at the rear of the box.

# 2739. Re: Additional Line Losses Due to SWR

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-27 05:16:22 UTC
From: "George, W5YR" <w5yr@att.net>
Message-ID: <G4Upd.63327$7i4.34315@bgtnsc05-news.ops.worldnet.att.net>
Source record: 86136

Keep in mind that real ohmic and dielectric losses measured in watts depend upon sqrt(SWR). Thus, the higher the SWR (load mismatch) the greater the I^2R losses in the conductors and similarly in the dielectric.

So, to me, a non-unity SWR connotes real power loss measurable in watts and attributable to well-known loss mechanisms.

Of course, any real power lost in the line materials represents power not delivered to the load, so this fits somewhat with the viewpoint that Line Loss is in fact the magnitude of power undelivered to the load due to the mismatch. But, I think that we are looking at real watts of loss here.

Another confusing factor is that one is usually interested in the total loss attributable to the use of a mismatched line and not especially in how that loss is distributed along the line from load to source. But there are applications where the loss distribution with line length is of concern. An example is the case of a complex Zo with rho > unity in which the majority of the power loss occurs in the section of the line nearest the load and decreases toward the source. In that case of probably limited application, the line nearest the load might be required to handle more power than that further toward the source.

A somewhat related example concerns the W2DU balun in which is it observed that the beads nearest the mismatched load endure the largest heat dissipation and are commonly larger that the remainder further toward the source.

However, since complex Zo is an issue of magnitude usually only at low r-f and more so at audio frequencies, this is seldom a practical consideration.

Thanks for bringing this topic to light, Bob. Like most engineers, I have been guilty of looking at "line loss" as a monolithic phenomenon and not being concerned with the micro-structure of its distribution.

Thanks for the feedback folks. Doc is on the right track. THe tuner works really well (way to go SGC, nice product!) and the antenna length doesn't seem to be impeding transmission distance.

Furthermore, the length, although not electrically correct for all frequencies, is convenient physically for a sail boat.

Glad to hear that the 1000 mile distance I attained was acceptable performance. My actual planned use is for keeping in touch with other vessels (friends) that are within a couple of thousand miles tops. Hopefully it will do the trick.

Thanks for the feedback folks. Muuch appreciated.

Source record: 86139

I have a MFJ 864 SWR/power meter. It has
two main circuits - 1.8-60 mhz & 144/440 mhz.

I'm working on the HF section, trying to make
sure it's correct. I have a known good power
meter and a 1:1 load.

If I set the forward power to 5w, can I get away
with hooking up the meter backwards to read
reflected power?

I set forward power to 5 w then reversed the
connection and adjusted for 5 w reflected.

Is this ok?

You can connect the wattmeter/swr meter either way. If hooked up
"backwards" then the forward and reverse scales become reversed.

You can adjust the 5 watt reflected power by hooking it up in reverse into a
dummy load and use a calibrated meter in series with it just as I think that
is your question.

Exactly what I was going to suggest. This will be easy to do if you have a
pully on the top end so you can easily drop the wire to change the shorting
straps. With the 50 foot wire, I would be concerned about getting high angle
radiation on 10/15/20 metters. Dog bone insulators might put less capacitive
loading on the top of the disconnected section.

How about adequate performance and convenience?

Ever been aboard an ocean going sail boat when the waves hit 5 meters and the wind is howling like a freight train? If not you can't imagine the fury. I've been there. It's exhilirating but not easy to endure. In fact it's damned hard work. That is NOT the time to be playing with knobs and switches trying to tune for a particular band. Believe me, I will have more imporant things to do. But I do want to know that I can tranmsit immediately if something terrible happens by just keying the mic. No fuss.

No offence but I've always been intrigued watching amateur enthusiasts wiggling knobs and waggling switches. Reminds me of a scene from the wizard of oz for some reason. Seems so unnecessary in this day and age.

CONVENIENCE is a VERY good a reason as any to use a tuner. And they're not all that costly either. A few hundred bucks at best.

Just my 2 cents worth.

Jimmy

In what world does an "L network" not equal exactly what a tuner does
for a wire antenna? An autotuner is nothing more than a binary
incremented L Network with autofeedback of directional power, and phase.
You suggestion is the same thing with no feedback or incremental changes.

# 2747. Re: Additional Line Losses Due to SWR

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-27 18:03:11 UTC
From: Frank <ve6cb@NOSPAM.telus.net>
Message-ID: <zj3qd.216349$9b.60519@edtnps84>
Source record: 86145

Modeling a free space dipole made from a lossless conductor, 100 ft in length, at 1.8 MHz shows an input impedance of 6.694 - j1621 Ohms. As expected the radiation efficiency is 100%.

Adding 300 ft of 600 Ohm, 6" spaced, copper open wire transmission line degrades the radiation efficiency to 16.75 %. The result, therefore indicates a transmission line loss of 7.76 dB. The input impedance is calculated as 11 - j619.7 Ohms.

The ARRL, DOS based program, "TL" computes, for 300 ft of 600 Ohm line terminated with 6.694 - j1621 Ohms, a loss of 8.19 dB, and an input impedance of 18.35 - j805 Ohms.

Realizing that 6" spaced, #14 AWG, is not exactly 600 Ohms, and NEC's computation of parallel wire transmission lines is not 100% accurate; the results do seem to confirm the validity of the ARRL's program.

Another interesting experiment with the ARRL's program also seems to verify its accuracy:

RG8, 1000 ft, frequency 100 MHz. Matched line loss = 24.82 dB.
Load impedance 1 - j1000 Ohms. Total line loss = 61.82 dB.
The program computes the input impedance to by: 50.3 - j0.2 Ohms.

73,

Frank

With a 50' antenna length and an adiquate RF Ground, one could
consider that a respectable Marine Radio Installation.

One thing that needs to be understood is that ALL Autotuners
have a REALLY BIG difficency that is inherent in their design.
They can NOT tune wires at the Half Wavelength point and 50Khz on each
side. At this point antenna impedance becomes Infinite and can't be
tuned. so a boater must make sure that he never intends to transmit
on the frequency that is at the electrical Half Wavelength of the
antenna. He may need to lengthen ot shorten the wire to adjust
for this condition.

S-meters are nothing else but power (input) meters.

Amateurs and meter manufacturers long ago learned, that when giving signal strength reports, it is more convenient to refer to meter indications in terms of S-units rather than micro-watts or nano-watts.

At HF, when the meter reads S-9 the power entering the receiver is 50 pico-watts. There's a slight complication above S-9 when the meter scale changes to decibels above S-9.

When the reading is S-9 plus 40 dB the meter is actually indicating about S-16. It's just a matter of scale graduations and printing.

The S-meter does NOT measure or even indicate field strength. It indicates nothing except that an increase in meter reading corresponds to an increase in field strength. Which may be nice to know but by how much of an increase is anybody's guess.

Measured field strength depends on the type of antenna, its efficiency, ground losses, etc. It is possible, of course, to calculate field strength in the vicinity of the antenna from S-meter readings provided the antenna, its directivity, transmission line, tuner and ground characteristics are all known numerically. Which in the amateur situation they are seldom not! Or even in the professional situation.

You've all got one. To repeat - the S-meter is a power (input) meter.

Hi James,

Well, as to the DX range, that has been responded to. So, to add to
all the comments in regard to height of antenna, tuners, automatic
tuners and the rest - another comment.

Take a fishing reel full of the Wireman's Flex weave (no doubt this
will provoke comments about wire corrosion) and drive it. Use your
hoist to pull out the correct height for any band.

I do take note of your admonition about fumbling with knobs, dials,
switches when a rogue wave is overtaking you. Your knottage may vary.

Thanks for the words of wisdom Bill.

In fact I made a point of purchasing a tuner that comes in a water tight (read that water PROOF according to the manfacturer) case. It's high up mounted in a lazerette that "theoretically" stays dry. The ground and antenna stud are both 316 Stainless (highly corrosion resistant and intended for use in salt air). Furthermore, the electrical connection between antenna stud and wire is soldered, crimped, and then heat shrunk with adhesive lined shrink. Instead of using high tension wire for the antenna connection to the backstay wire, I used tinned copper heavy gauge insulated electrical wire. The environment that I live in is so corrosive that, believe it or not I had to strip back the jacket to expose the tinned copper wire, and then seal the cut edge of the jacket to prevent salt water ingress between jacket and wire. If that isn't done even tinned copper wire will corrode. Salt water will creep under the jacket and corrosion will occur for a few feet distance from the

stripped jacket.

All connections (RF, power and control) between tuner and radio are made with crimp and solder, then sealed with liquid electrical tape, then adhesive lined heat shrink. I bought really big insulators to go at both ends of the wire antenna too. Salt water is conductive and the larger insulator with heavy ribbing will hopefully reduce the surface coating of salty water to a level that precludes conductivity. Hopefully. the copper wire I ran up the mast is on it's own pulley (well it will be when I find time to go up the mast) and is already a lovely shade of green. I have a spare, and hope this one lasts a year before needing replacement.

Even so, I expect to have to service the connections about once a year or so.

And you thought putting a beam on a tower was hard! Just thought you'd find the lengths we have to go to in the ocean environment interesting.

The KISS principle is followed where ever I can too. I sincerely agree. When things go badly on board, it's rarely one big bad thing that bites ya. It's a string of small problems that...when combined, lead to a bad day. I guess that's true in a lot of endeavors come to think of it. Last time I was in a bad storm (a really bad one at that) I was on the radio seeking information from someone else who had radar (I do not). My autohelm had failed (a lousy 25 cent pin broke) and so I had to hand steer in heavy seas. I couldn't leave the wheel. Fortunately the mic on my marine VHF radio ~just~ reached the wheel from inside. Unfortunately that is when I discovered that if I pulled on the mic cable it became very intermittent. And that led to me spending a half hour trying to raise a nearby boat with radar to ask which way the storm appeared to be moving. Then the lightning started hitting the water all around me...from there...well...let's just say it went downhill some.

Simple is good.

Thanks again for the feedback.

Dear Richard,

I'm finally ready to comment on the above - it is my great fortune to be blessed with copies of both the Fourth and Fifth Editions of the ITT Handbook.

I studied over the first 13 pages of Chapter 22 and found that, just as Wes said, it's entirely the work of MacAlpine as published in 1953.

I went over Equations (1) through (4) in the Mismatch section very carefully and found no heartburn with anything in that section. This is NOT to say that I LIKE it, but I do understand it and have no problem with the math model and the figures. My problems with the two mismatch topics is simply that I just don't like to call it a loss when energy that COULD have been delivered to the load does NOT get delivered to the load as a result of mismatch. For me, lost energy in a transmission line problem is energy actually lost in the transmission line, not energy that is being lost elsewhere as a result of the transmission line not being matched properly. I realize that I'm probably alone in that thinking, but I like to feel that such terms as efficiency and losses should be associated strongly with the

item under evaluation, namely the transmission line, and not the ancillary equipment which feed it or terminate it. Those items get their own hearings relative to efficiency and losses and those evaluations do not require the presence of the transmission line. In fact, those items are usually evaluated as to their performance in ways that do not in any way relate to how well some transmission line is or is not working.

However, this is not the nub of the problem that I was encountering - a problem which has now been partly resolved. At least I think I have a far, far better understanding of the problem now than I had a few days ago. The problem centers on the Additional Losses Due to SWR and how to model them. Since it is, perhaps, more appropriate to continue that topic under the responses from Wes, I will not go into it here.

I want to thank you and Wes, both, for leading me to Chapter 22 - it is much more readable than MacAlpine's original paper.

Dear Wes,

I was happy to find that the MacAlpine paper is the first part of
Chapter 22 of the ITT Handbook, as the latter is much more readable.

I did not pick up on the MathCad files, because I do not have MathCd -
however, the material from MacAlpine and Ricardi have answered most of
my concerns.

>|I hope that MacAlpine agrees with what Dave and Richard are telling

I was premature in those two paragraphs, above. I can see now that the
Additional Losses Due to SWR really are dissipative and are unrelated
to the "Mismatch Losses" and "Transducer Losses" defined on page 22-12
of the ITT Handbook, 5th Ed.

>Yes it is. A simple-minded way of looking at it is if the SWR is
>greater than unity then increased current is flowing in the line. The

>VSWR) so there are peaks and valleys in the current and as you have
>figured out, the longer the line and the higher its nominal loss, the
>lower the ISWR is at the line input.

My interpretation of your "Yes it is." is that you mean that the
Additional Losses Due to SWR are truly heat losses and are due to the
ohmic losses in the hot spots of the line. Then we agree on that
point. Your paragraph above is much more succinct than the papers by

MacAlpine and Ricardi, but it certainly tells the story.

>So the loss per unit length is non-linear and varies with distance
>from the mismatch, but it is a real dissipative loss.

I don't know that I would have used the term "non-linear", but I would certainly agree that it varies along the line in accordance with the current loops.

>For those interested in the loss in the shorted or open stub case,
>maybe this will be of interest:
>http://users.triconet.org/wesandlinda/Stub_Matching_Loss.pdf

I took that pdf and added it to the collection. There were several things about that paper that filled-in gaps of detail in MacAlpine. However, neither paper gives us much hope for a simple model of these losses. Nonetheless, it makes hash out of the material in The ARRL Antenna Book. In all fairness, the Antenna Book cannot cover all aspects of these topics in detail. Unfortunately, the material in the Antenna Book is, in my opinion, very misleading in several specific areas, as follows:
- The Antenna Book gives only one expression for Total Line Loss (combining ML loss and the Additional Loss Due to SWR). If we accept Macalpine's model, there are different relationships for the range of SWR from 0 to 6 and for the range from 6 upwards.
- Antenna Book does not explain that the hot spots are very localized and that the additional losses can be quite dependant upon the length of the line in wavelengths. For example, the losses in a segment of line less than 1/3 wavelength might be insignificant in comparison with a segment of line greater than 1/3 wavelength simply because the shorter segment may not contain a hot spot. In other words, one cannot apply the Antenna Book equations, blindly, because of several factors that are not even mentioned, and for short line segments it is quite possible that there would be no signicant losses due to SWR.
- The most misleading information in The Antenna Book is on pages 24-11 and 24-12 where it is shown that a 100 foot RG-213 feedline will suffer 25 dB of Additional Loss Due to SWR at 1.83 MHz because of the very short antenna. I believe that when the equations from the ITT Handbook are used instead, that the actual losses will be far, far less.

Just today, I made a careful measurement on an RG-8/U line of 5.33 meters length at 30 MHz and terminated with a 4700 + j 0 load. The Matched Line Loss of that line at 30 MHz is 0.9 dB per 100 feet, and its Velocity Factor is between 0.75 and 0.80 The input impedance was actually measured at 2.45 -j15 ohms for an SWR at the input of 22.25. The SWR at the load end was 94. Those two SWR's establish a total loss on the line of 0.15 dB. If one were to blindly apply the formula in The Antenna Book on page 24-9, the result obtained would be 4.323 dB.

Easy answer. Do a web search for Trigonometry angle solver and you'll discover that quite a few people have written little web sites where you can enter in side-side-side lengths or side-angle-side and the remaining angles and side lengths will be caluclated automatically.

I've used them. Don't feel bad, most of us have long forgotten trigonometry.

Jimmy

Rise = 34-8 feet = 26 feet
hypotenuse = 73 feet

angle = arcsin of rise/hypotenuse = arcsin (28/73) = approximately 20.9ï¿½
between the ground and the wire.

The angle between a vertical support at the apex and the wire is then
90ï¿½-20.9ï¿½ or 69.1ï¿½

Make a right triangle, with the sloper as the hypotenuse. One apex of the triangle is the higher sloper wire end. Go straight downward from there 34 - 8 = 26 feet to form the second side of the triangle. Then go from there straight horizontally to the lower sloper wire end to form the third side. The following isn't to scale, but it should give you the idea. View it with your browser set to a fixed, not porportional, font:

```
/
/ |
sloper / |
73' / | 26'
/ |
/ |
/__A_____________|
```

The answer to your question requires basic trigonometry, usually taught in high school in the U.S., so 6th grade math won't quite cut it. Of course, you could draw it to scale on a piece of paper and use a protractor to determine the angle, and that would be adequately accurate for most purposes.

Angle A is the angle the sloper is tilted upward or downward from horizontal. The sine of an angle in a right triangle = the length of the side opposite the angle divided by the length of the hypotenuse, which for angle A is 26/73. So we know that the sine of A = 26/73 = 0.356. In this day and age, the way to find the angle once we know its sine is to use a (scientific) pocket calculator. The function we want is "arcsin", "ASIN", "inverse sine", or "SIN^-1", all of which mean "the angle whose sine has this value". I notice that the calculator which comes with my XP operating system (in the Accessories folder) has this function. If you have one in your operating system, first make sure the "Degrees" selection is made in the upper right (assuming you want the answer in degrees). Then enter .356 into the calculator, check the Inv box (so you'll get the inverse sine), and finally click the "sin" button. The answer, with a ridiculous number of digits, is about 21 degrees.

You don't have to take a course in trig to learn and use the basic functions sine, cosine, and tangent, which are just ratios of the various sides of right triangles. (The cosine is the length of the adjacent side divided by the length of the hypotenuse, and the tangent is the length of the opposite side divided by the length of the adjacent side.) With that knowledge and an inexpensive (or free) calculator, you can easily solve problems like this.

Hi Zack,

Well, not 6th grade material, but for my students in the Navy (and I
sure didn't invent this memory aid):

For the conventional usage
S sine C cosine T tangent O opposite A adjacent H hypotenuse
where you choose one corner or angle (but not the right angle) of any
right triangle and the terms mean:
O the length of the side Opposite that angle
A the length of the side Adjacent to the angle
H the length of the Hypotenuse

O
S = ----
H

A
C = ----
H

O
T = ----
A

What kept it in memory. Reading down columns gives
S C T O H A H O A
or
Sally Could Tell Oscar/Had A/Hard On/Always

You know the Opposite (26) and the Hypotenuse (73) which would give
you the sine (0.3562), take the arcsin of this value to find the angle
(21ï¿½).

About 21 degrees. For calculation purposes, mentally move the antenna down 8 feet. So you now have a triangle with altitude of 26 feet and a hypotenuse of 73 feet. The sine of the angle you want is 26/73 or .3562. The cosine of .3562 is 20.86 degrees.

If you don't frequently use what you have learned, it evaporates. I know exactly how you feel.

73,

SOH CAH TOA

Sin = Opposite over Hypotenuse
Cos = Adjacent over Hypotenuse
Tan = Opposite over Adjacent

34-8=26

So the Opposite is 26
the Hypotenuse is 73
Sin(theta) = 26/73 = 0.35616438356164383561643835616438

So Theta = ArcSin(0.35616438356164383561643835616438) =
20.864823641018812055586761532415 degrees

Or somewhere close to 21 degrees, if you're into rounding.

Hello All -

This reads like a tongue-in-cheek bit of good-natured trolling... but I have added a few comments, just in case some newbie takes it all too seriously.

"Reg Edwards" <g4fgq.regp@ZZZbtinternet.com> wrote in message news:coafls$slt$1@sparta.btinternet.com...
>
> S-meters are nothing else but power (input) meters.
>
Actually, the tradition has been to characterize S-meter calibration (if I may call it that) in terms of voltage, not power. Of course, the two may be translated freely if one assumes an input impedance.

More significantly, the typical signal-strength indicators on receivers are not ANY kind of "meters"--in the sense of comprising calibrated test equipment. A minority of higher-end receivers MAY receive a quick stab at meter calibration in the alignment process; and they MAY have flat enough gain versus frequency for that calibration to apply roughly across their frequency coverage. But I wouldn't count on it.

> Amateurs and meter manufacturers long ago learned, that when giving signal

Amen to that.

> At HF, when the meter reads S-9 the power entering the receiver is 50
> pico-watts. There's a slight complication above S-9 when the meter scale
> changes to decibels above S-9.
>
The "at HF" qualifier is curious, since the propositions are not frequency dependent. But 50 pW does indeed match up to the traditional 50 uV, if I did my math right.

> When the reading is S-9 plus 40 dB the meter is actually indicating about
> S-16. It's just a matter of scale graduations and printing.
>
A very important omission here is the traditional assumption that each S-unit should represent a 6 dB change. My FT-1000D shows substantial departures from this ideal, BTW.

But since the S-unit scale is an attempt to quantify the S1 through S9 range of the classic RST signal reporting scheme, there is no such thing as "S units" above S9, the highest. Hence the "dB over" nomenclature.

S-meters are relative signal strength indicators. Some of them MAY match
the "ideal" response at a few input levels and input frequencies.

So I cant resist

We had a similar discussion on the VK-VHF NG (a closed NG). The general consensus for VHF/UHF SSB use as summarized by Gordon VK2ZAB was;
---
The scale is:
S9 = -93 dbm = 5 uV into 50 ohms.
S8 = -99 dbm = 2.5 uV
S7 = -105 dbm = 1.25 uV
S6 = -111 dbm = 0.625 uV
S5 = -117 dbm = 0.313 uV
S4 = -123 dbm = 0.156 uV
S3 = -129 dbm = 0.078 uV
S2 = -135 dbm = 0.039 uV
S1 = -141 dbm = 0.02 uV - Note that this fortuitously corresponds to the level, on Earth, of the power due to thermal noise in a bandwidth of 2000 Hz.
And if you like:
S0 = -147 dbm = 0.01 uV
S-1 = -153 dbm = 0.005 uv
S-2 = -159 dbm
S-3 = -165 dbm
S-4 = -171 dbm
S-4.5 = - 174 dbm Note that this fortuitously corresponds to the level, on Earth, of the noise power due to thermal noise in a bandwidth of 1Hz.
Those that wish to do so may exercise their arithmetic skills by determining what S point and /or dbm level corresponds to the noise power at say one [1] degree above absolute zero - which may exist somewhere in space.
---

Note that there was a lot more discussion about the use/misuse of S meter reports. I thought the scale the more useful though.

Cheers Bob VK2YQA

True enough -- "cosine" above should be "arcsin". The arcsin of a number is the inverse sine, or the angle whose sine is the number. Cosine is a different trigonometric function, defined by a ratio of different sides than the sine.

==========

Bob asked -
> However, just to satisfy my curiousity, exactly which of your
> beautiful, zipped up Pascal programs will do that for me?

==========
Bob,

I thought nobody would ever ask. But they've been available from my website for years.

Look at Programs -

RJELINE2
RJELINE3
RJELINE4
COAXPAIR
COAXRATE

and give yourself a few practical examples.

There is a one-line description after each program's name on the download page in my website.

The above programs are dedicated to transmission lines. Input data includes one or two physical dimensions which avoids restriction to particular type-of-line numbers. Users are given a free hand to design cables to their own specifications. Nevertheless, they are practical in nature and simple to use. There are other programs which incorporate the same calculations but which are not explicitly apparent to the user.

They use exact classical transmission line formulae and so are as accurate as the input data over the stated frequency ranges. Usually from power frequencies up to UHF. They take skin effect and the increase in inductance at low frequencies and other subtle factors such as conductor proximity effect in twin-lines in their stride.

They are good enough for the highest precision engineering applications. I have not disclosed the source code to prevent it falling into the hands of argumentative vandals, so-called guru's, and technically ignorant old-wives who would ruin the programs' reputation, not forgetting mine, for RELIABILITY. Reliability is Quality versus Time.

For references I quote my only tutors - Ohm, Ampere and Volta.

When considering transmission lines you can check your's and other programs against mine for accuracy with confidence. You will discover the effects of both your known and other, unsuspected approximations.

Readers should bear in mind I'm not getting paid for this.

Bob, I'm on MontGras, Chilean, Reserve Merlot, tonight. Nuff said.

You cannot do that. Even on a good meter (like a spectrum analyzer or an EMI receiver), the meter is calibrated only for input power at its front panel connector. You still have to add a frequency dependent correction factor for cable loss and antenna efficiency. Very expensive measurement systems operate under computer control, with a calibrated analyzer and the computer adding the appropriate factors for cable loss and antenna factor. (This allows for flexibility; a different coax or antenna can be substituted at any time, so long as the computer has a table of factors for the new device.)

As for how you mark the S-meter scale, I agree that we use an archaic system with S-units. It would be more rational to use a simple dB scale referenced to something like 1 picowatt (which would then become 0 dBpW). OTOH, the purpose of an S-meter is not to provide absolute measurements. It is used as a tuning indicator and for relative signal strength comparisons. And the archaic marking system works fine for that need.

Hi Bob -

Thanks for your input!

I can understand the basic idea of a VHF/UHF offset for the "S-scale,"
based on the much lower ambient noise levels in that frequency range.
Twenty dB seems like a pretty large offset, though--but who am I to tell
the VK-VHF crowd how to do their "S-scale?" ;-)

Roger on your themal noise estimate. It's been a few years, but I recall
using -114 dBm/MHz as the thermal noise level back in my radar design
days. That would track with your figure. But S1 for you is 0 dB SNR
with a 0 dB NF? Wow, you VKs must have good ears!

Yes, I agree with your comments, and am familiar with EMC and ATR
measurement techniques. Mentioning dBuV/m was a bit tongue in cheek, but
just the same if you could add the antenna factor etc. it would be nice to
give accurate reports of field strength. Still dBm (or dBpW) is certainly
no big deal. Even if not laboratory accurate, it still means so much more
that the S signal strength scale.

# 2779. Inverted V Noise Problem

Newsgroup: rec.radio.amateur.antenna
Date: 2004-11-28 06:20:56 UTC
From: Warren Bowery <kc8ykq@arrl.net>
Message-ID: <Xns95AFDB0EA6C2wbowerybrightnet@216.196.97.142>
Source record: 86076

Hello, all....

My first HF antenna (still in use) is an inverted V cut for 40 meters. This very quiet antenna is constructed suspended from three trees in front of my home - the tree in the middle supports the apex while two somewhat evenly spaced trees support the ends. The center of the antenna is approximately 30' above the ground, and the angle of the V is about 120 degrees. The antenna is constructed of #14 stranded jacketed wire fed with 450 ohm window line. This antenna has worked quite well for me on 10-40 meters using a transmatch.

Several months ago, I tried to raise the antenna's center to around 40'in order to improve performance. I also raised the antenna's ends proportionately. My transceiver's noise level increased dramatically. I then tried a "flat top" dipole configuration without any lessening of the noise. When I returned my antenna to its original configuration, all was quiet again. To me, the noise sounded electrical in nature.

There is a power line feeding a street lamp about 25' away and perpendicular to the original dipole. The street lamp power line is about 35' high. Power lines to all of the homes in our neighborhood are buried except for the home adjoining our back lot. The power company strung a conventional pole-to-house feed to their home. The feed to the street light also runs from this pole.

I am planning on stringing an 80 meter dipole in our back yard. This new antenna would be constructed of the same components, and parallel to my original wire antenna. The apex would be strung between trees with the middle about 40' above the ground. However, I am leery of doing this project considering the noise problem experienced when I raised my original antenna. I would like to add a 80/75 meter antenna however.

Is my problem related to a noisy power line feeding the street light, or is it be something else?

Thanks in advance for your suggestions!

Warren - KC8YKQ

Warren -

To solve this kind of problem in the real world, you need to eliminate things one by one.

With the antenna back up in the noise, see what happens when the street light comes on at dusk - is this when the noise starts? Or is the noise there before the light turns on?

If it's there without the light, some device in your neighbor's house may be sending the noise back up the power line. Thermostats, fishtank heaters, yard lights - the variety of noise sources is impressive.

Could also be loose or rusted connections on the pole/transformer.

You might be able to trace the source with a pocket transistor radio tuned between stations.

ARRL has some good stuff on interference - have you checked their website?

Would like to hear other opinions on this one - I'm still learning.

Warren,

You may not have a problem.

The signals level MUST also have increased with the increase in height.

Did the signals go up together with the noise, the signal-to-noise ratio
remaining unchanged?

Reg - any increase in signals certainly did not increase enough to overcome
the noise. Like I mentioned, the original configuration I is very quiet.
In fact, the noise level went from not registering on the meter at all at
the lower height to an S9+ when I raised the antenna.

Gidday Bob

Thanks very much for replying to my questions.
I take it then, that if you connect a screened cable between the aerial and the receiver, the length of the cable itself does not act as an aerial because the screening prevents this?
So if the aerial is only one "core" where do I connect the screen? I know I could connect it at the aerial end to the car body (earth) but what about at the receiver end? Does it have to connect at all at that end as long as the screen is connected to the car body?
By the way, the car itself will be stationary and switched off so hopefully I won't have the problem of interference from the car electrics.
Also the transmitter is apparently fixed frequency 100-125MHz and the receiver switched to this.
I'll experiment and see!
Let me know if you have any thoughts about the screen.

Thanks again

Iain (Scotland)

To the above, add the photocell on the street light. depending on how
it was designed, it could make noise waiting to turn 'on', or when 'on'.

Bill,
In most cases, anything you do on a boat is a compromise between what it 'ought to be' and what's possible. Since the backstay (or frontstay) is ~there~ anyway, why not use it? Certainly not the 'best' thing in the world (whatever that is), but 'better' than most alternative$.
Some people have a 'phobia' about tuners. If you don't want to use one, that's fine. They do make 'things' much easier and the difference in performance is 'acceptible' in most cases (acceptible being relative). Since there are alternatives, pick the one you think you can 'live' with and go with it. "You pays your money and takes your choice", as they used to say in the house with the red velvet wall paper...
'Doc

PS - Not that I've ever been in one of those houses, I've just read about them...

For your 1/4WL open stub on 10.6 MHz, with a stub impedance of 0.57 ohms,
I calculate total losses of about 0.2 dB.

Hi Warren,

Then it appears you upset the balance of the antenna (hard to believe
it was balanced before) such that common mode noise is finding its way
in.

It seems entirely unlikely that you achieved any more gain, nor more
highly resolved angular discrimination to now be focused on a source
of noise that has "always" been there.

The way I read your statements, it's as if you raised your antenna to
the equal horizon of a noise your antenna in its former position just
couldn't see. At HF and at those heights, this just isn't in the
cards. Signal intensity follows square law and for your noise to rise
from nothing to S-9 does not correspond to any dimensional change (or
if it does, there's your clue, but you are within inches of it now
where you were 10's of feet away formerly).

Sounds to me like its a not so simple case of more power line noise coupled into the antenna at it increased height, which at its new height is also closer to the height of the power line. But the comments about the large difference in noise observed and also the contradiction to the square law effect are interesting.

Maybe the question we should be pondering is NOT what the changes in the antenna pattern are, but what the antenna pattern of the *power line* at the observed freq is. These things are by nature antennas as well which also exhibit directivity and gain (I'm cringing at the thought of future BPL "dx"), but would probably be impossible to model since there are too many unknowns.

So my 2 cent theory is that the original antenna location lies in a power line noise pattern null (or no low angle) and at the new height it's now in a lobe.

Dear Cecil,

I hope I'm not misinterpreting your values - I assume that you are
starting with a theoretical open circuit and a theoretical RG-8 line
and calculating a theoretical impedance seen looking into that line of
0.57 + j 0. From that you then calculate a theoretical 0.2 dB. When I
say calculate, I assume that you may instead by using a nomogram.
Anyway, based on all of that being the situation up to but not
including the loss figure, when I take the 0.57 + j0 and calculate the
SWR as 87.7 I get a loss more like .05 dB, theoretically, so I'm not
sure in what ways we are coming up with these numbers. I can explain
exactly how I got mine, which was via measurements followed by a
theoretical cacluation of loss based on the two SWR's formula which is
built into all Smith Charts.

Who the heck are Ramo and Whinnery. Never heard of them! Presumably,
because you refer to them, they are or were people who make or made a living
out of re-iterating old wive's tales in book-form.

It was obvious I introduced G = C * R / L simply to show that a line's Zo
can be purely resistive even when it is NOT lossless. It can have any loss
you like.

Apparently you have not yet grasped the idea.

And, despite what R and W or YOU may have to say on the subject, it is an
exact expression at all frequencies from DC to almost infinity.

My only references are Ohm, Ampere and Volta who I'm sure you have heard of.

But no hard feelings. ;o)

Tonight I'm on Chilean, dry, 2004, MontGras, Reserve Chardonnay. I didn't
choose it myself. My loving daughter does my shopping. But it's quite a
pleasant, refreshing plonk.
----
Regards, Reg.

Hi John,

The simple wavelength mechanics of that negate the premise. For any structure, much less a power line, to exhibit a null due to a dipolar distribution; then that would have to arise from certain constraints. Chief among them is isolation from ground by a significant portion of one wavelength, in this power line case 5000000 meters.

However, the noise is not 60Hz. In the case of the actual frequency of the interference, it is equally unlikely to be emanating from the power lines - from the 60 Hz generation end. It would necessarily be emanating from a load that is using the line as an antenna (although, not purposely except in your nightmare of BPL).

In this case of higher frequency nuisance, the same powerlines would present an enormously long structure (unless the noise were snubbed at the nearest isolation transformer). that would create a huge number of lobes. And still, it is unlikely that any null to peak of those lobes would match the characteristic of no noise to S-9 variation. As such, the odds are on square-law ruled proximity. Where in quieter times past the noise was 10's of feet away, with change that noise got within inches. That, or the description of noise levels has been exaggerated.

A noise survey should be performed with a simple handheld transistor SW receiver. Walk around and listen. If push comes to shove, then tie a string to the receiver, turn up the volume and hoist it up. More can be determined by this than all the arm-chair prognosis.

>of the ITT Handbook, 5th Ed.

Hi Bob,

I've let this simmer for a while, but I have to return to this because
you've erred in interpretation of this particular page and those
particular subjects. They are entirely caloric losses, not what you
dismiss as the myth of mismatch loss.

You need only review the math offered to observe they use the
conventional "real" line loss and add more "real" line loss in
proportion to the reflections at either one or two interfaces. The
equations are quite literal to this and explicitly state:
A0 = normal attenuation of line

If you want deeper math, one source can be found in Chipman's (as
unread as any here) "Transmission Lines."

This is yet another of my references that attend to my recent, short
thread on the nature of power determination error, and mismatched
loads AND sources. In fact ALL of these references I've offered
explicitly describe that the source MUST be matched for ANY of these
equations about transmission lines bandied about to accurately offer
true answers. The naive presumptions that Source Z is immaterial to
the outcome of analysis is quite widespread here.

Chipman offers the rigorous math that attends explicitly to the Smith
Chart loss nomograph you reference elsewhere in this thread. If you
lack access to this work, I can munge up the equations here for you.
I will add, this math is for "lossless" lines, as is the implication
of the Smith Chart nomograph; but it only requires you to add that in
for yourself by restructuring the math to include loss. At that level
of granularity, it won't be pretty; but you can rest assured it will
be complete.

You should replace the copper wire with the stuff the BIG BOYS use.
It is called Phospher/Bronze Antenna wire and it Doesn't turn green
when in contact with Seawater or salt air. Stuff was designed for this
spacific purpose.

And without the rubber, the flex and bending of the antenna gets directly transferred to the sma connector. You'll be wishing you'd had some sort of support before long, as the rig is in the shop with a broken sma connector. Stephens connectors work well, I've had one for years, and think it was one of the smarter accessories I've purchased. (Ft-50)

Not using a nomogram but everything is 100% theoretical. It doesn't
matter what line is being used as long as it's Z0 is 50 ohms. Matched
line loss didn't enter into my calculations. It's only total loss.

> Anyway, based on all of that being the situation up to but not

> SWR as 87.7 I get a loss more like .05 dB, theoretically, so I'm not
> sure in what ways we are coming up with these numbers.

Is that the additional loss due to SWR or the total loss? My theoretical
loss is total loss and the matched line loss need not be known. The
measured resistance of the resonant stub is all one needs to know besides
Z0.

> I can explain
> exactly how I got mine, which was via measurements followed by a
> theoretical cacluation of loss based on the two SWR's formula which is
> built into all Smith Charts.

I can't remember where the following formula came from. I think it
was from an RF guru at Intel, but I can't be sure. I have a hand-
written notebook of useful formulas covering 25 years but I didn't
record where they all came from.

The formula for theoretical TOTAL losses in a *resonant* stub:

Total loss = 10*log{[(Z0-R)/(Z0+R)]^2}

where R is the measured resistance of the resonant stub and Z0
is the characteristic impedance of the stub material. You can
see the [(Z0-R)/(Z0+R)]^2 term is akin to a virtual rho^2 at
the mouth of the stub. Since rho^2 = Pref/Pfor, the losses in
the stub are equivalent to the losses in an equivalent resistance
equal to the measured virtual resistance at the mouth of the stub.

Hi Iain

Without going into a lot of transmission line theory.... <grin>

For the purposes of this post, coax is the same as "screened cable". I'd suggest you use coax though (RG58 will do) as its impedance doesnt vary along its length and it is a known value... unlike plain screened cable.

When you setup a radio in a car the antenna attachment on the radio end is normally a coaxial connector. The centre conductor goes into the "live" part of the box and the screen goes to the metal chassis of the radio itself. At the antenna end the centre coax conductor connects to the whip itself and the screen is connected to the car body at the point where the whip starts. The whip is of course insulated from the car body.

In a correctly installed and tuned installation (usually the whip length) the coax doesnt pickup any noise.

You dont need to connect the radio end screen to the car body. In your case you might be able to use a nearby metal screw on the radio. The last alternative maybe to use the negative power line where it enters the radio. The idea is to get the screen connection as close to the receiver input ground as possible. The more exposed centre conductor there is at the radio end the less efficient the system is.

Given the frequency you have mentioned a "good" whip length will be around 570mm. There are of course a number of unknowns in setting up this system so dont try playing with the whip length too much.

Cheers Bob VK2YQA

Ramo and Whinnery are the authors of my 50's college textbook on fields and waves. Of course it could be a misprint, but they say your above formula is an approximation that is good for low-loss lines.

Apparently, something additional happens for high-loss lines. Chipman seems to agree with Ramo and Whinnery when he introduces some additional interference terms (discussed some time ago on this newsgroup). At the time, I didn't realize the additional terms were interference terms but the impedance of the load apparently somehow interacts with the characteristic impedance of the high-loss transmission line to upset the ideal relationships in your equation above.

And single-banded, one thing a tuner is not. :-)

The antenna need not be resonant. Under certain easily obtainable
conditions, the length of the open-wire transmission line can tune
a non-resonant antenna to system resonance and better the losses in
the coax feeding a resonant antenna. How to do that is described
on my web page.

In other words, replace the stub with a resistor having the same
value of measured resistance as the stub, and calculate the I^2*R
losses in the resistor. That will be the same value as the total
losses in the stub.

Back to TX distance - you really need to get a good book on propagation and understand the solar cycle and the characteristics of each band.

For example -- on 10M with the right time in the 11 year solar cycle -- a minimum antenna and a few watts will work the world (at the right time of day)

On 160M in the day time in the summer with low power -- you ain't going anywhere

It's kind of difficult to get a resonant quarter wave into a back stay
as you don't usually know where ground is. Ground can be any number of
feet from where the feed point is on a boat. Every thing above real
ground is antenna.

Bill I agree But
The original poster sed:

"My very first contacts were established with 2 land stations on 14300 at
100W that were about 1000 miles away. They both reported that my signal
was good and that it sounded like I was "sitting right next to them". I
have no idea if this was a good distance, great, or mediocre."

So I assume he was after contacts of several hundred (thousand) miles - not
ground wave.

My point was this for the 160M band (From a book on propagation)

"160 meters. Daytime conditions for this band suffer from extreme D-layer
absorption, reducing the amount of signal to levels far below the noise
floor of our receivers. This limits daytime coverage to essentially
ground-wave coverage. At night, the D layer dissipates rapidly and worldwide
160-meter communication becomes possible via the F2-layer and in ducts in
the electron density valley above the E region peak. Depending on the
propagation mode, high or low elevation angles may be required. A limiting
factor is the noise levels prevalent at these frequencies, both atmospheric
and man-made as well as tropical and mid-latitude thunderstorms which cause
high levels of static in the summer season. Winter conditions are much
better, making winter evenings the best time to work 160-meter DX.

So you might have ground wave on 160M during the day to 100 miles or so.

See URL for details and formulas on ground wave distances
http://www.qsl.net/g3cwi/Downloads/Propagation%201.doc

As I sed --- way too much on propagation to put on a post and cover all the
variables and details -- the original poster needs to get a good book or at
least look at this free URL
http://www.ae4rv.com/tn/propflash.htm

And of course -- "on 10 meters at the
> bottom of the sunspot cycle 10 is open nearly every day to
